THE

Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VIII.] JANUARY 1, 1889. [No. 85.

Our Portrait Gallery.

JONATHAN HUTCHINSON, F.R.S.

THE London Hospital at Whitechapel, by its close proximity to the London Docks, where thousands and thousands of labourers are employed, and where accidents are continually occurring, affords the student opportunities of witnessing surgery which few London hospitals can offer. The district, moreover, covered by the London Hospital, densely populated, known by the name of the East End, is composed of an essentially working class population, for whom hospital aid is essential; so, whilst the surgical side is but too well supplied with cases, the medical side is also plentifully furnished.

The following summary of patients for the year 1887 will show the value of the London Hospital in the treatment of accidents and diseases:—

IN-PATIENTS ADMITTED.

Free	Accidents	2,321	6,019	8,260
	Urgent extra cases	3,638		
Recommended by Governors and Subscribers			2,241	

OUT-PATIENTS.

Free (including 7,321 accidents)	74,296	95,760
Recommended by Governors and Subscribers ...	21,464	

From these figures, the place occupied by the London Hospital among public charities will be gathered. It is, in reality, the largest institution of the kind in this country, having a complement of 776 beds.

As a teaching institution, apart from the beneficent work for which the hospital really exists, the London stands unrivalled, whether we look to the celebrity of the teachers or to the clinical material available. The considerable increase in the number of students has resulted in the enlargement and improvement of the College building in 1879, and in the almost entire rebuilding of the College buildings in 1886. The new building is now in occupation, and was formally opened on May 21st, 1887, by Their Royal Highnesses the Prince and Princess of Wales. It might seem invidious to mention individual names connected with the teaching staff when all have claim to mention, but certainly one of the best known is the subject of our illustration, who is now Consulting Surgeon to the Hospital. A brief history of his life work, as given in *Men of the Time*, and in Churchill's "Medical Directory," will fully establish his claims to the position we assign him.

Jonathan Hutchinson, F.R.S., was born at Selby, in Yorkshire, 1828, and educated at Selby. He was admitted a Fellow of the College of Surgeons in 1862; he was appointed President of the Hunterian Society in 1869 and 1870; President of the Pathological Society in 1879-80; of the Ophthalmological in 1883; and was Professor of Surgery and Pathology in the Royal College of Surgeons from 1878 to 1883.

This distinguished surgeon was a member of the Royal Commission appointed in 1881 to inquire into the condition of the London hospitals for small-pox and fever cases, and into the means of spreading infection. Mr. Hutchinson has written works on the following subjects: "On the Form of Dyspepsia which usually attends Phthisis;" "Clinical Memoir on certain Diseases of the Eye and Ear consequent on Inherited Syphilis" (1862); "Surgical Diseases of Women," in Holmes's *Syst. of Med.*; "Transmission of Syphilitic Taint from the Fœtus to its Mother;" "On Constitutional Syphilis," Reynolds's *Syst. of Med.*; "The Rectangular Catheter Staff for Lithotomy;" "The Astley Cooper Prize Essay for 1865;" "On Injuries to the Head," *Contrib.*; "Clinical Illustrations of Amaurosis;" "Lesions of the Eye in connection with Injuries, etc, to the Fifth Nerve;" "Illustrations of Clinical Surgery;" "Clinical Lectures on Rare Diseases of Skin, and on Gout and Rheumatism;" and numerous other papers. He has also lately brought out a manual on "Syphilis;" is on the Council of the College of Surgeons, and was chosen this year to deliver the Bradshaw Lecture.

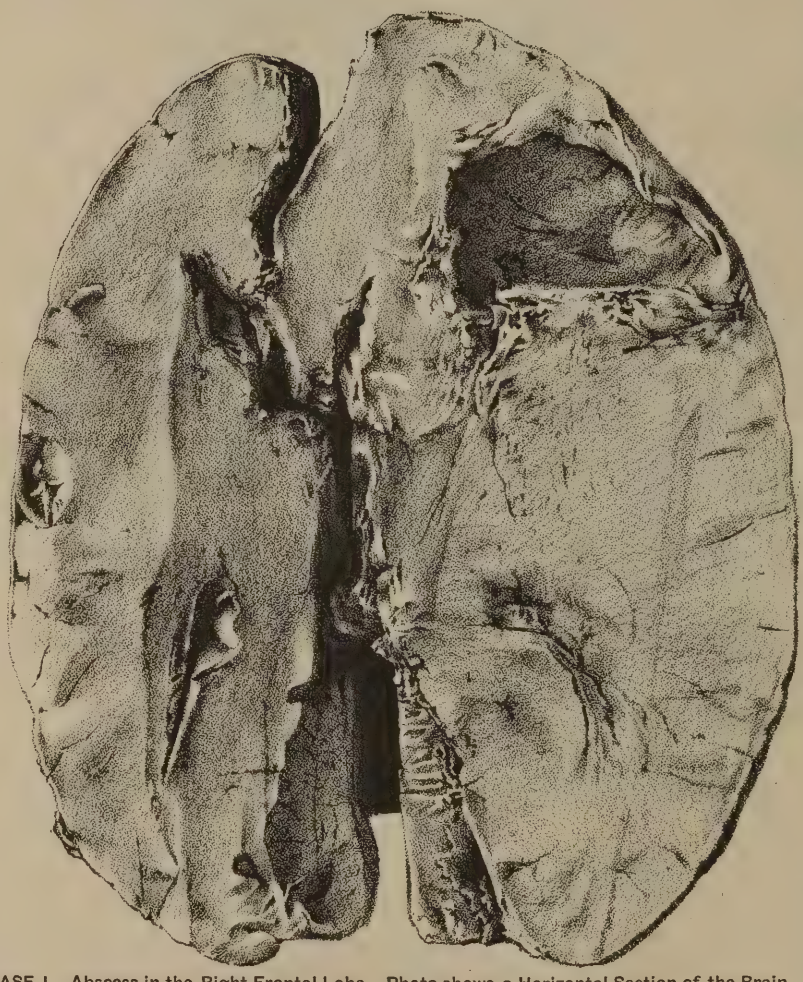
Original Communications.

NOTES ON FIVE CASES OF INTRA-CRANIAL ABSCESS, WITH ILLUSTRATIONS.

By C. J. BOND, F.R.C.S.,
SURGEON TO THE LEICESTER INFIRMARY.

CASE 1.—*Abscess of Right Frontal Lobe.—No Ascertainable Cause.*—S. M——, female, æt. twenty, married, one child. No history of syphilis or tubercle. Present illness began three weeks ago by vomiting after food, accompanied with, and followed by, great frontal headache. On admission patient is continually sick after food; the vomiting is preceded by a sharp pain referred to the stomach. Complains of constant severe frontal pain, exacerbations of which, are accompanied with passing slight lividity of face. Patient lies either on her back or side with eyes semi-closed; answers simple questions rationally, but very slowly, and on pressure; never volunteers any remark, and takes little notice of her surroundings, appearing like a person who wishes to go to sleep, and to be left alone. No tenderness or hyperæsthesia of scalp; pupils rather dilated, react to light. Temperature, subnormal. There is no local paralysis.

One week after admission there was an internal squint of the right eye, with diplopia; vomiting continuous. The mental apathy gradually increased, and the patient now lies on her right side with her legs drawn up. An attack of tonic spasm occurred a few days later, in which the right upper limb was strongly flexed at elbow, wrist, and finger joints, with supination of hand, and the left arm was extended along the abdomen. Death occurred from coma.



CASE I.—Abscess in the Right Frontal Lobe. Photo shows a Horizontal Section of the Brain, and the marked deviation of Septum.

Post-Mortem.—No signs of disease in any organ except the brain, in the right hemisphere of which, in the white matter of the right frontal lobe was an abscess the size of a pigeon's egg. This was situated in front of the level of the motor area, and was separated from the outer surface of the brain by a thin layer of grey substance. The contained pus was crowded with micrococci, singly, and in chains. The abscess had caused marked asymmetry of the hemispheres, pushing the septum between them well over to the left side. No excess of fluid in the ventricles.

CASE 2.—*Abscess in Right Temporo Sphenoidal Lobe following Disease of Tympanum. Rupture into Lateral Ventricle.* A. B——, æt. seventeen; has had discharge from both ears for some years; a large mass of granulations was removed from both sides on February 27th. On the following day patient was admitted, there was some staggering in the gait, chiefly to the right side, and severe occipital headache. Four days later there was some pain on percussion over the right temporal bone, but the staggering gait was much better; also the headache. About 7-30 p.m. the same day, however, severe vomiting came on. The temperature, which had been averaging 99° to 100°, rapidly rose to 106°, and the breathing became stertorous; pupils dilated, and patient rapidly became unconscious, and died comatose in eleven hours.

Post-Mortem.—Both tympanic cavities disorganised and full of cheesy material. On the right side the roof was perforated, and at this spot the brain was adherent to the *dura mater*. At a corresponding part of the right temporo-sphenoidal lobe, at a distance of a quarter of an inch from the surface, was an abscess the size of a walnut, and this abscess had also opened into the descending cornu of the lateral ventricle, this and the lateral ventricle on the same side containing a quantity of purulent fluid. There was also some recent lymph in the posterior cerebral fossa, where the cerebellum came into contact with the petrous bone, but no pus.

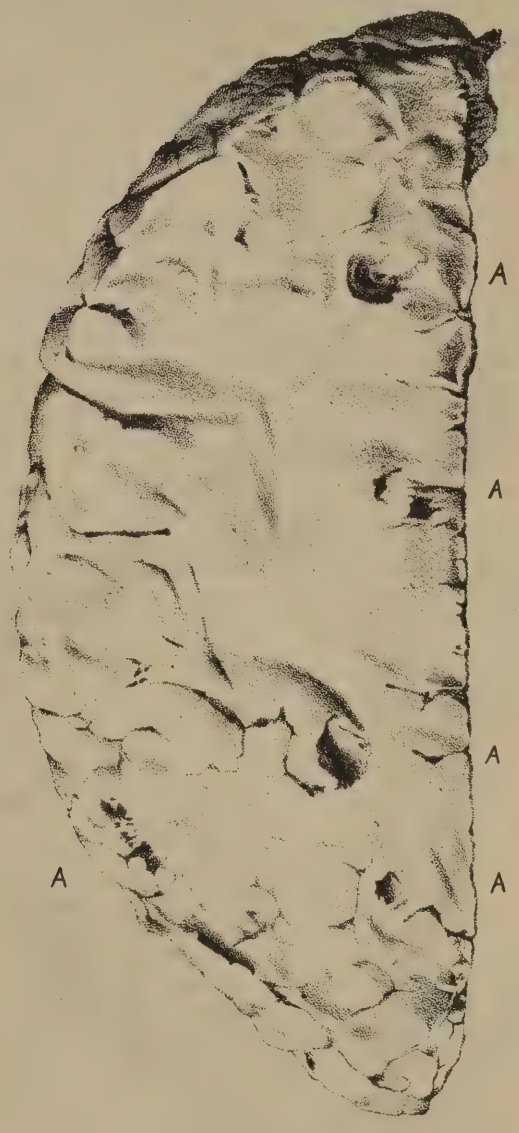
CASE 3.—*Abscess of Left Temporo Sphenoidal Lobe following Disease of Middle Ear. Previous Obliteration of Left Lateral Sinus by Old Clot.*—A. A——, æt. twenty-six. Patient, a healthy sailor, has had discharge from the left ear for three years. Three months ago he suffered from symptoms referable to the disease of the ear—namely, rigors and severe headache, with high temperature; no delirium or convulsions. He, however, recovered from this condition, and was as well as usual until four days ago, when he began to complain of pain in the left frontal and temporal regions, more acute in the former. There is nausea, but no vomiting; temperature normal. Patient is slightly giddy on movement. On February 8th, under

$CH\ Cl._3$, the left mastoid cells were opened by a gouge, but no pus detected. On the following morning patient was conscious, but mumbled somewhat in his speech. He rapidly became unconscious, and died the same afternoon.

Post-Mortem.—Left tympanic cavity full of cheesy material, with perforation of the roof and adhesion of the brain to the *dura mater* at this spot. The whole of the inner portion of the temporo sphenoidal lobe was greatly inflamed, reddened, and softened; and at one part, close to the uncinate convolution, and bordering on the crus cerebri, the softening had reached the stage of disintegration, an abscess cavity with ill-defined walls having formed. The lateral sinus on the left side was completely obliterated, and filled by a very tough, closely adherent, white, fibrous clot, reaching from the torcular herophylli to the left jugular foramen. The clot was, in fact, closely incorporated with the walls of the sinus, showing it to have been at least of some months' duration. No signs of disease in any other organ.

CASE 4.—*Multiple Cerebral Abscess following Pleuro-Pneumonia, with Empyema.*—W. D——, aged twenty-eight, a previously healthy man, had been ill fourteen days, and on admission was found to be suffering from symptoms of pneumonia at the base of the right lung, and pneumonia with pleural effusion on the left side. This pleura was incised a few days later, and a large quantity of very offensive thin pus evacuated. The patient now rapidly improved; the discharge lessened, and the temperature gradually fell to normal, and remained so for three weeks, all the signs of pneumonia disappearing. On February 28th, seven weeks after the operation, patient began to complain of severe headache, chiefly in the forehead and vertex; the temperature rose suddenly to 103°, and continued to rise each evening to 102° or 103°, falling in the morning to about 100°. There was no local paralysis, or twitching of the face or limbs; no optic neuritis; urine, acid, passed naturally; no albumen. Patient had some delusions connected with his employment, that of groom, and rambled at night. He knew his friends, however, and there was no affection of speech, or special sense; reflexes, patella increased. Patient gradually became unconscious, and died comatose on March 10th.

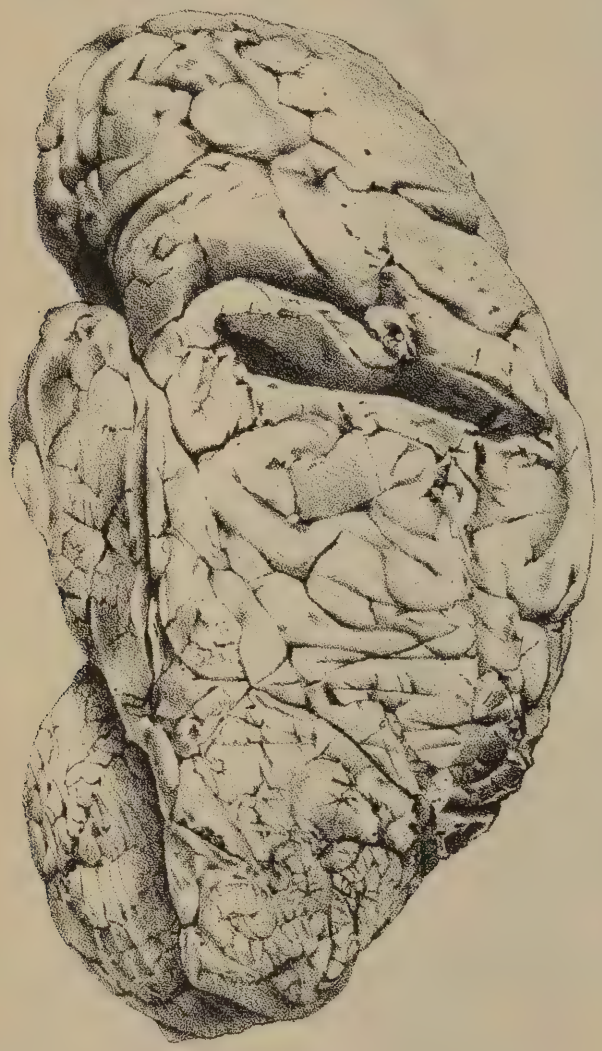
Post-Mortem.—The cavity of the empyema on the left side had shrunk very much, and would only hold a couple of ounces; it was nearly empty, well drained, and non-offensive. The left lung, though somewhat collapsed, had expanded considerably, and showed no signs of pneumonia. Right lung healthy, with the exception of some hypostatic congestion at the base. *Brain:* No meningitis. Scattered throughout the cerebrum (both hemispheres) and the cerebellum (both hemispheres) were numerous abscesses—thirty to forty—varying in size from a pea to a large nut. They contained a green, non-offensive pus, and were situated in the white matter; the smaller, and apparently more recent ones, for the most part, at the edge of the white matter, many of the larger ones encroaching on the grey matter by their advancing growth. A portion of the upper part of the spinal cord was examined and found to be healthy. No abscesses or signs of disease in any other organ, with the exception of some congestion of both kidneys. Though the abscesses were scattered irregularly throughout the whole remaining portions of the hemispheres, very few were detected in the white matter bordering the motor area on either side. A careful microscopical examination of the pus taken from several abscesses, and stained by Koch's method, showed a considerable number of micrococci in each specimen; in many places these were arranged in chains.



CASE 4.—Multiple Cerebral Abscess following Empyema. Photo shows a Horizontal Section of the Left Cerebral Hemisphere, with Abscess Cavities in the White Matter—Abscesses (a).

CASE 5.—*Traumatic Abscess in Left Ascending Parietal Convolution.*—B. W——, female, æt. forty-three, fell down while partially drunk eight days ago, and struck her head on the left parietal region. She did not loose consciousness, but got up herself and went to bed. Next morning she noticed a sensation as of "pins and needles" in her right hand, and this was accompanied with some loss of power in the limb. She, however, went to her work (chairwoman) for the next six days, and on the seventh day complained of headache, and came home from work. On the eighth day her speech was a little "thick" in the morning, and twitchings occurred in the right corner of the mouth; half an hour later her right hand and arm began to jerk, and three hours later, on admission, the

right leg was also in a state of clonic spasm, with increased patella tendon reflex. About six hours later the spasm had entirely ceased; the speech was clear, and patient was quite sensible. It was, however, noticed that on any sudden noise occurring in the ward, such as the slamming of a door, the clonic spasms slightly reappeared. The history of the case after this date is one of gradually increasing, and at last total hemiplegia of the right side, with aphaxia. The patient lived twenty-two days after the injury, and died comatose.



CASE 5.—Traumatic Abscess in the Left Hemisphere, corresponding in position with the Left Ascending Parietal Convolution; the grey matter over the Abscess Cavity has been removed.

Post-Mortem.—Showed the presence of a small scalp wound, which had healed, and beneath this a punctured fracture of the skull, with projection inwards of a spicule of bone from the inner table, opposite the middle of the left ascending parietal convolution. At this spot the *dura mater* had been pierced, and was adherent to the underlying cerebral cortex. Immediately beneath this was an abscess cavity containing non-offensive yellow pus; it was pyramidal in shape, with apex pointing downwards and inwards, in the direction of the white fibres of the cortex. Its base corresponded very accurately [see photo] with the outline of the ascending parietal convolution. No general meningitis. No signs of disease in any other organ.

Remarks.—The above five cases, although recorded very briefly, present some points of considerable interest. In Case 1 no cause could be found for the abscess in the frontal lobe, and I also have a photo of another brain, showing an abscess in a similar position in an otherwise healthy male adult. It is curious that putting on one side cases of abscess due to disease of the nose, which was absent in this case, most of the cases recorded as having no apparent cause, such as pyæmia, lung disease, injury, or otitis, are examples of abscess in the frontal lobe. Thus Adams records a case of double frontal abscess in the *Lancet* of 1862; and in Maudsley's case (*Lancet*, 1865) the disease probably originated in front of, and only subsequently invaded the motor area. At any rate there seems to be some common condition underlying these cases of abscess of the frontal lobes, at present unknown.

In Case 2 the abscess in the tempero sphenoidal lobe burst into the descending cornu of the lateral ventricle. The sudden collapse was probably due to this, and the high temperature perhaps followed on the absorption of putrid pus by the peritoneal-like cavity of the ventricle.

Case 3 is the only one for which the writer is responsible for the treatment; the mastoid was trephined, and it was determined to trephine the skull over the temporo sphenoidal lobe on the following day, but the sudden death of the patient prevented any treatment being carried out. This case clearly shows that obliteration of the lateral sinus on one side is in no way fatal, and probably produces little or no symptoms when brought about gradually, as in the pathological way by formation of clot.

Case 4 adds one more to the recorded list of cerebral abscesses following disease of the chest, and especially empyema. There are several suggestive facts in connection with the abscesses in this case. Their great number (thirty or forty), comparative small size, their position, in the edge of the white matter bordering on the grey cortex, or lining of the ventricles, and the way in which the white fibres of the motor area escaped. The peculiar bright green character of the pus, and the presence of micrococci in the pus. The appearance suggested the idea of a crop of abscesses, arising over a limited period of time, and originating in perhaps some embolic process, septic particles which had originated in the lung tissue bordering on the empyema, having become lodged in the brain. If it could be proved that the capillaries vary in size in different parts of the cerebral hemisphere, being smallest in the grey and larger in the white matter, and larger still in the white matter of the motor or middle cerebral area, this theory would receive considerable support. It is also suggestive that cerebral abscess occurs generally at a somewhat late stage, when the empyema is closing, and the lung expanding; while in other cases the lung affection has been bronchiectasis, pneumonia, and in a few cases fibroid phthisis; cases for the most part in which there have been small collections of putrid fluid in cavities, bounded by dense walls, surrounded by lung tissue. How far the expansion of the lung after empyema, and its movements in respiration help to dislodge the septic thrombi, must be at present only conjectural.

Case 5 is of interest from the unusual limitation of the abscess to one important wedged-shaped area of motor cortex, represented externally by the ascending parietal

convolution; the morbid process underlying the symptoms spreading from the injured portion of brain in the centre, (see photo) upwards to the leg centres, and downwards to the face centre. The reinduction of the clonic spasm by the stimulus of noise is also worthy of note.

A general survey of these cases of abscess seems to point to the general conclusion—that, as in the case of tumour (see Provincial Medical Journal, Aug. and September, 1888), so also the process of suppuration occurs in the white fibres rather than in the grey matter of the brain. Even in the cases due to injury, or in cases following suppurative otitis, it is very common to find a portion of comparatively sound grey matter, between the injured bone or the necrosed tympanum, and the broken down white matter beneath.

SUGGESTIONS FOR THE MORE RATIONAL THERAPEUTICAL TREATMENT OF RESPIRATORY AFFECTIONS.[1]

By C. Clark Burman, L.R.C.P., L.R.C.S. Edin.,
Belford, Northumberland.

(*Continued from page* 544.)

It may not be out of place to look at the differential diagnosis of these three forms of asthma, idiopathic, cardiac and pulmonary (as distinguished from idiopathic). In each, the successful treatment will depend upon a proper differentiation; and as, sometimes, the urgency of the case calls for prompt action on our part, we ought to be prepared to look for the salient features of each, and thus judge how best to treat them.

Idiopathic asthma is characterised by the absence of all those well-known symptoms connected with chronic cardiac or pulmonary complaints—the patient during the interval is perfectly well—his recovery is perfect when the paroxysm ceases; active exertion causes no unpleasant symptoms; thus differing from the cardiac and emphysematous forms, and enables us to form a comparatively easy diagnosis. But to discriminate between the two latter forms, say mitral disease and chronic bronchitis with emphysema, greater care is needed before coming to a decision. Not unfrequently both causes are combined, and then the diagnosis is still more difficult, and we must look to the preponderance of one or more symptoms to aid us in forming a conclusion. In uncomplicated cardiac cases, such as mitral stenosis or dilatation, so often met with as a sequel to acute rheumatism, scarlet fever, etc., we find the breathing free and easy when no exertion is made; when it is attempted, a panting, gasping form of breathlessness is experienced, constituting the "air hunger" of the Germans; so great is the difficulty of getting the blood aërated, from the pulmonary engorgement resulting from exertion. Again, in some forms of cardiac disease depending more upon muscular degeneration of a senile character, rather than valvular lesion like the former, the patient wakes gasping and alarmed from his sleep, he has palpitation, angina, irregular action, and frequently the attack ends by vomiting. Here the cause of the sudden dyspnœa is the feeble heart not being able to force the blood sufficiently quick through the pulmonary vessels to carry on the oxygenation process; in both the cause is identical, in one it is due to a damming back of the blood; in the other, the propulsive power is feeble; in both, the dyspnœa relieves the condition, for the time at least.

In chronic bronchitis with emphysema, we find the thoracic cavity is so distended by the dilated pulmonary vesicles, that expiration is greatly deficient, the residual air is not sufficiently changed, and a more or less constant state of respiratory embarrassment is met with. It requires greater inspiratory force to enlarge this already expanded cavity, and the loss of that elasticity in the pulmonary tissues which executes the expiratory act requires the assistance of the accessory muscles, so that we find a patient suffering from emphysema *always* breathing heavily; and this difficulty is greatly increased upon exertion, since the respiratory act must be so deep that it is necessarily somewhat prolonged, and one long breath to such a patient is of much more use than frequent short ones. Therefore we find emphysematous patients slow in all their actions; they must have time even for breathing, and any cause which necessitates or produces rapid breathing distresses them very much. We judge, therefore, in such cases of the pulmonary over the cardiac origin by the state of respiration during rest, in one tranquil, in the other permanently embarrassed. A patient sooner recovers from an attack of emphysematous asthma than cardiac asthma, for the distended right ventricle requires some time to recover itself, consequently he is longer in experiencing relief; in the latter case it is not only a question of getting the blood oxygenated, but, in addition, the excited action of the heart set up by over distension, has to be overcome. As I have already mentioned, the explanation of these attacks is found in the reduction of respiration both in depth and frequency during sleep, and especially that of the first sleep, which is more profound than that of the early morning. Mönninghoff and Piesbergen, two of Vierordt's pupils, ascertained by experiment the depth of sleep, using as a sensory stimulus the auditory sensation produced by dropping a lead ball from a given height. For a perfectly healthy man, during the first hour the slumber is very light; after one hour and a quarter the depth of sleep increases rapidly, reaches its maximum point at one hour and forty-five minutes, then falling quickly to about two hours and a quarter, and afterwards more gradually; but later on, after four hours and a half, there is a second small rise, which reaches its maximum at five hours and a half, and gradually falls again until the time of awakening. If we compare the time when attacks of nocturnal dyspnœa come on, I think we shall find a marked correspondence between the depth of sleep and the paroxysms. The gradual depression of the breathing permits the carbonic acid to increase in the blood from less frequent interchange, and at the same time facilitates the engorgement of the lungs when the propulsive power of the heart is deficient (for venosity of the blood causes slowing of the cardiac rhythm), but only to the extent of rousing the respiratory centre to an action more or less excited; and where from long standing stimulation, as in chronic cases, the centre has become accustomed, to a certain extent, to an excess of carbonic acid, it responds less readily; yet a certain point is reached when its activity is roused, and violent dyspnœa is the result.

[1] [To the writings of the late Dr. Milner Fothergill, whose recent decease the profession still mourns, I must express my great indebtedness, not only for suggesting the line of thought I have endeavoured to follow in this paper; but also, as the readers of his works will observe, by the numerous quotations, for the actual words in which to express my meaning. I take the opportunity, therefore at this stage to fully acknowledge this assistance in a general way, and thus avoid a repetition of references. For further information I would suggest a careful perusal of the following works of Dr. Milner Fothergill: "The Antagonism of Therapeutic Agents," "Chronic Bronchitis," "Handbook of Treatment," "The Physiological Factor in Diagnosis," and "Gout in its Protean Aspects."]

I will only call to remembrance the remarks I have already made regarding the danger of giving drugs, either as sedatives to the whole cerebral centres, or more particularly, drugs which have a double action, upon both the reflex and automatic and higher centres; when a proper discrimination of the causes producing the dyspnœa might suffice for the administration of a drug which renders a sedative unnecessary.

Uræmic dyspnœa.—Any description of respiratory embarrassment would be incomplete unless reference was made to this form. It is met with in patients suffering from lithiasis in one of its protean forms, perhaps not during an acute attack, but more frequently as a sub-acute condition superimposed upon a chronic gouty state of health, when the heart presents the signs of hypertrophy, and the arteries are markedly "corded" to the touch. Again, we must not forget that not unfrequently bronchitis, of a purely gouty origin shows itself, and fails to succumb to ordinary treatment unless the cause is attacked in combination with expectorant remedies. The case of the late Lord Beaconsfield was an example of gouty asthma, and attracted attention from the fact that most relief to the paroxysms was received from a secret remedy called "Himrod's." Whether the irritation of the bronchial mucous membrane is due to the vicarious action of the membrane, assisting the excretion of those nitrogenous products usually removed by the kidney, or whether the impure condition of the blood renders the membrane more easily inflamed, is perhaps not sufficiently well known; most probably the first is the reason. The fact of gouty bronchitis associated with attacks of dyspnœa, or of gouty patients, in the later stages, being subject to attacks of severe nocturnal dyspnœa without bronchitis accompanying them, is sufficiently recognised; and it may be instructive to look at the pathology of these attacks with a view to successful treatment. The presence of nitrogenous products in excess in the blood may be, and perhaps is a potent factor in the causation of these attacks. Owing to this condition, it is possible that the elimination of carbonic acid is checked until it accumulates to the extent of rousing the respiratory centre to extensive discharges, setting the accessory muscles of respiration into action; or whether the arterio-capillary fibrosis, producing a high state of tension in the capillary system, may now and then produce a state of spasm of the pulmonary vessels, thus leading to interference with the proper oxygenation of the blood, is still an open question. But from the effect of certain drugs in attacks of uræmic asthma, such as nitrite of amyl and nitro-glycerine (which are undoubtedly useful in reducing spasm of the smaller arteries), one would look upon the latter as a likely cause. On the other hand, many cases of this affection yield in a very satisfactory way to respiratory stimulants, when the gouty condition is attacked by alkalies and hepatic stimulants to rouse the functional activity of the liver (which is, according to recent researches, largely implicated in the formation of uric acid), and, at the same time, the well known property possessed by the skin of relieving the disorganised and over-taxed kidneys is taken advantage of. The chief point in treatment is the recognition of the gouty cause. The fact of the bronchial mucous membrane, assisting in the excretion of nitrogenous elements, is found in the proof afforded by holding a glass slide, moistened with hydrochloric acid over the mouth of a patient in a state of coma from chronic renal disease, when white crystals of chloride of ammonium are formed. This may be but one of nature's methods for reducing the poisonous state of the blood by an attack of dyspnœa, when the excited respiration will assist in depurating the blood; so that a plan of treatment which will render the respiratory act more effective will be a useful adjuvant to the stimulation of the skin and liver, which is usually done.

Cheyne Stokes' respiration consists in "the occurrence of a series of inspirations, increasing to a maximum, and then declining in force and length, until a state of apparent apnœa is established. In this condition the patient may remain for such a length of time as to make his attendants believe that he is dead, when a low inspiration, followed by one more decided, marks the commencement of a new ascending and then descending series of inspirations." At one time this rhythmic respiratory derangement was held to belong to the fatty heart solely, but it is now recognised as occurring under a variety of circumstances; it belongs to vascular conditions, and to affections of the cerebral hemispheres; it is also found in uræmia.

This phenomenon, of such grave prognostic importance, is readily explained by the feeble cardiac action (due either to muscular degeneration of its walls, as in fatty heart, or to feeble action, the result of some cerebral cause, as in cases of cerebral apoplexy, or in uræmia by the hypertrophied left ventricle failing and yielding before the strain produced by the high tension in the smaller blood vessels, or perhaps by malnutrition from the vitiated state of the blood) permitting pulmonary engorgement and insufficient aëration of the blood; and as the respiration itself has been, in most of the above mentioned disorders, in an unnatural condition for some time, the excitability of the respiratory centre has become diminished from exhaustion consequent upon long continued effort to keep the blood purified. A considerable increase in the venous state of this fluid is required each time in order to excite it, and we notice the gradually increasing respiratory acts until the climax is reached, and the powerful respirations which eventually appear having thus renewed the blood to an extent whereby the amount of oxygen is sufficient to prevent any further activity on its part, we find a gradual decrease, until at last a momentary cessation of breathing takes place, and the exhausted centre remains quiescent until roused from its lethargy by the demands of the system; though the stimulus required becomes greater and greater to effect this discharge of nervous force, until at last the centre, having become completely exhausted, refuses to respond, and death ensues.

We could not look for stronger evidence as to the indication for treatment. The flagging respiratory centre must be roused by one of the class of respiratory stimulants, while at the same time the cardiac conditions, so very frequently associated with the phenomenon, must be met by appropriate treatment. Might I not carry my suggestion further and say, that the same treatment holds good in those cases of cerebral apoplexy accompanied by embarrassed respiration with accumulation of mucus, so frequently leading to pneumonia, due no doubt to the imperfect respiratory act. We might look for benefit from such remedies as render the act more perfect, since the diaphragm is never paralyzed, while many of the accessory muscles are only in a state of paresis, not paralysis, and capable of being roused into action by a vigorous stimulation. In cases of hemiplegia, where a liability to pneumonia exists, either hypostatic or from increased intra-thoracic secretion, it is of the greatest importance, during the stage of unconsciousness and during convalescence, to make a point of changing the patient from

one side to the other, so that the secretions, if they cannot be then expectorated may, at least, by the simple force of gravity, be kept in the lung of the side upon which the patient is lying; and by frequent changing, the lungs are called into action equally, and the secretion is not allowed to remain long enough in one lung to permit of changes ending in consolidation. It is a plan I invariably adopt, and is useful both in the hypostatic and other forms, while the respiratory action is stimulated by one of the class of remedies already referred to. The beneficial results of frequent changing from one lung to another were extremely well seen in several cases published some time ago in the *British Medical Journal*, where the patients were undoubtedly saved from asphyxia during the period preceding the return of consciousness by this means.

The extreme value of the vicarious action of the skin when other excretory organs, particularly the kidneys and liver, are unable to carry on their function either wholly or partially, is thoroughly recognised in medicine. It will be instructive to consider the relation between pulmonary and cutaneous respiration. Hermann says:—"Respiration, properly so called, which consists in the interchange which takes place between the gases of the blood and those of the atmospheric air, has its seat wherever the blood capillaries are in intimate contact with the latter medium. This occurs at the external surfaces of the organs of respiration, and in addition, at the skin, and in the alimentary canal, which always contains air, though in both the latter. the process goes on with feeble intensity. In some animals, however—*e.g.*, in frogs, cutaneous respiration is of such importance that, after the lungs have been removed, it suffices by itself to supply the small quantity of oxygen which the animal requires."

Carpenter, in his work on "Human Physiology," says: "The aëration of the blood may take place, not only by means of the lungs but also in some degree through the medium of the cutaneous surface, which presents an extent of 1,500 square centimetres." . . . "There is also evidence that the interchange of gases between the air and the blood, through the skin, has an important share in keeping up the temperature of the body; and we find the temperature of the surface much elevated in many cases of pneumonia, phthisis, etc., in which the lungs seem to perform their function very insufficiently." (pp. 376, 377, ninth edition).

Looking at the vicarious action of so many different organs of the body, instances being found in the diarrhœa of uræmia (to check which, before the renal functions are established, is fatal); the exhalation of ammonia and other nitrogenous compounds in the breath of patients suffering from chronic renal disease; the elimination of bile by the different emunctories when the gall duct is obstructed from catarrh, impacted gallstone, tumour, etc., and many others easily enumerated, naturally leads us to the supposition that in the well-marked embarrassment of the respiratory function during phthisis, and other pulmonary affections, the extensive area of blood-vessels in the skin comes to its aid, and acts vicariously. The profuse sweats of phthisis are well-known to occur when the sleep is profound and coma-like, and that, when the patient remains awake the perspiration is less. I have repeatedly stated that the respiratory action during sleep is neither so frequent nor so deep; and, when from the long continued activity of the respiratory centre it is more or less exhausted, may we not look upon this cutaneous action as compensatory, supplementing the pulmonary deficiency. But this cutaneous action is an expensive way of aiding the lungs; the amount of blood salts which escape during the profuse sweats of phthisis interfere materially with the nutrition of the patient, and while we attempt to check the amount of perspiration, we must not forget its compensatory action, and select those remedies, which, while giving the patient the benefit of retaining the valuable blood salts do not prevent the lungs becoming still further embarrassed by the restriction. The agents which would meet both these ends are to be found in a drug, which, while exercising a very marked influence over the sudiparous glands of the skin, at the same time so stimulates the respiratory centre that the changes in the lungs effect such an amount of purification of the blood as to abolish the necessity for the vicarious cutaneous action. Such a remedy is atropia, of which more hereafter. Meanwhile, let me call attention to the fact that opiates, given for the purpose of allaying cough or producing sleep in phthisical patients, invariably increase the sweating, owing to their depressant action upon the excitability of the respiratory centre, as well as by their direct diaphoretic action; it is already so wearied by its continuous efforts to secure, with a reduced amount of available lung tissue, those necessary changes in the blood to make life endurable, if not comparatively easy, that it readily succumbs to a dose which would, in health, have little or no effect upon it; the profound sleep induced still further aids in the respiratory depression, so that either an attack of dyspnœa ensues, or the patient (more frequently at least in phthisis), wakes up bathed in a profuse perspiration. If opiates or other sedatives must be given, and the indications for their use become less frequent when we really understand the cause of the restlessness and dyspnœa, they are to be guarded by combination with some respiratory stimulant which prevents the profuse perspiration (which inevitably occurs unless this is done) by doing away with the need of assistance from the skin, and permits the sedative to affect the higher cerebral centres, and relieve the cough, which is the principal cause of the sleeplessness.

Whooping-cough.—Unlike the act of coughing usually, we find whooping-cough connected with inspiration much more than expiration; at least, it is the inspiratory portion, so to speak, of the respiratory convulsion which gives to it its significance.

I think the evidence recently brought forward respecting this disease is strongly in favour of classifying it among those affections due to the presence of a bacillus; but our purpose here is rather to examine the relation of the paroxysm to the respiratory function, and from it endeavour to find, in the observance of the manner in which this function is interfered with, some indication for its treatment. I think a plan of therapeutics, having this for its guide, will be more successful than those founded on the various theories of its being an affection of the medulla, pneumogastric nerves, or a bronchial catarrh, or due to the presence of a microzyme, though I must admit, upon the latter theory, a treatment aimed at the destruction of those organisms supposed to lead to the specific manifestations should be more successful than one directed to the combating of these manifestations, were it not for the fact so well known regarding this disease, that slight causes, such as a mild catarrh, a chill even, or exposure to cold winds, etc., after the whoop has entirely ceased, will at once cause its re-appearance, due to the effects of habit, so to speak, of the respiratory centre—a nervous "trick," and not to a relapse of the original affection. In whooping-cough we do not have relapses but complications, and the

latter, when occurring during the later period of the second or paroxysmal stage cause it to be prolonged to an indefinite period.

On perusing the list of remedies extolled for the cure or alleviation of whooping-cough, their number is sufficient evidence of the different views held on the subject of its pathology; and so far, at least, we cannot claim to have discovered a specific for this disease. I think the most successful treatment will be found to consist, not so much in the rigid adherence to any set of formulæ, but in the careful calculation of the gravity of any one or more symptoms pointing to some of the many complications so frequent in its course; some due to external causes entirely, as exposure to cold, etc., others dependent on the violence or prolongation of the characteristic paroxysm. These complications may be nervous, as cerebral congestion with convulsions; pulmonary, as capillary bronchitis, collapse of portions of the lung tissue leading to catarrhal pneumonia; gastric, as persistent vomiting, leading to marasmus, or diarrhœa with similar results.

The main points, in my opinion, to which we should particularly direct attention in the treatment of whooping-cough is the character of the respiration and the frequency or severity of the paroxysms. From the first, we can decide whether respiratory stimulants are needed, as, for instance, when the breathing during the intervals is feeble, shallow, and frequent, or on the other hand is deep and strong, though frequent, but combined with an excited state of the vascular system, which would then point to the administration of one or other of the respiratory depressants, which likewise depress the circulation: while the frequency or severity of the paroxysms will guide us in the treatment by indicating whether the respiratory centre is becoming exhausted or remains able to do its work efficiently without assistance, or whether the administration of nervine sedatives is necessary to allay the extreme reflex excitability of the terminal ends of the vagi. Upon the due comprehension of the relative value of these different elements rests, I think, the successful treatment of whooping-cough, the death-rate of which is somewhat of a stigma upon the profession. No hard and fast line can be laid down for the exhibition of bromide of potassium, or of bromide of ammonium, belladonna, alum, quinine, or of the various forms of germicides, so-called. I shall refer again to this subject when I take up the consideration of the "Therapeutics of Respiratory Diseases" in general.

I must apologise for the length of my introduction, but the proper appreciation of my second part rests so much upon a thorough understanding of the various phenomena produced through the influence of the respiratory centre and its afferent and efferent nerves upon the whole mechanism of those disturbances of respiration, which are more or less the constant associates of diseases of the respiratory organs, that I have considered it almost a necessity to take them in detail, and though it may seem a waste of time to go over the well-known phenomena of dyspnœa, asthma, whooping-cough, etc., the increased light thrown upon them by recent research has materially modified our views of their treatment, and necessitates something of a recapitulation for the purpose of applying this newly-acquired knowledge to a system of therapeutics, advancing in proportion as physiological and scientific facts are laid bare; so that we may, by means of new light thus afforded us, adopt a form of treatment which will bring relief to our patients and credit to our profession—the two main objects we are all seeking to obtain.

(To be continued.)

RODENT ULCER OF FACE—REMOVAL—CURE.

By A. W. MAYO ROBSON, F.R.C.S.,

HON. SURGEON LEEDS GENERAL INFIRMARY; LECTURER ON PRACTICAL SURGERY AT THE YORKSHIRE COLLEGE; AND HON. CONSULTING SURGEON BATLEY HOSPITAL.

(REPORTED BY MR. C. F. M. ALTHORP.)

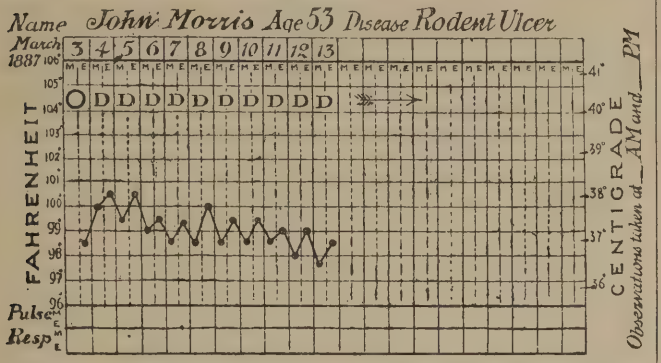
J. M——, æt. fifty-three, a turner, was admitted into the Leeds Infirmary on February 28th, 1887, under the care of Mr. Mayo Robson, suffering from a large excavated sore which occupied the right temporal region.

History.—About twenty years ago patient first noticed a hard pimple about the size of a pin's head, which appeared three quarters of an inch external to the outer canthus of the right eye. *Six or seven years after this* the spot began to ulcerate, there being no discharge at this time. The ulceration gradually invaded the neighbouring structures. During the last few years patient has been applying ointment, which has caused the ulcer to discharge a small quantity of thin pus. He has had no pain during the whole course of the disease.

Present Condition.—On admission there is a large excavated sore situated over the right temporal region, and extending from the zygoma for three inches in a vertical direction. The ulcer is square, with rounded angles, and measures three inches by three inches. It extends from the external angular process of the right frontal bone outwards for three inches. *The floor* of the ulcer is irregular, red, and indurated, the lower half being depressed, and the upper half heaped up above the level of the surrounding skin. It is smooth, rounded, and covered with small vessels. Scattered over the upper part of the sore are several small white nodules, which vary in size from the head of a pin to a pea. *The edge* of the ulcer is raised, indurated, and rounded. A small quantity of pus is discharged daily. The lymphatic glands are not affected.

Operation. — On March 3rd, patient being anæsthetised, Mr. Robson made an incision wide of, and surrounding the ulcer, and proceeded to dissect out the diseased mass. There was much bleeding; several vessels were ligatured, others being occluded by clips. The temporal artery was cut and ligatured. It was found that the ulcer was adherent to the malar bone, and also to the temporal bone, fæscia, and muscle. By means of raspatory and knife it was separated from the subjacent tissues and removed. The parts to which the ulcer was adherent were scraped, and bleeding was arrested by ligaturing several vessels, and also by pressure. Whilst the mass was being removed a quantity of thick curdy pus welled up from under the ulcer. Some of the fat under the

zygoma and malar bone was removed. When bleeding was arrested, the surface of the wound was dusted with iodoform, and a gauze dressing put on.

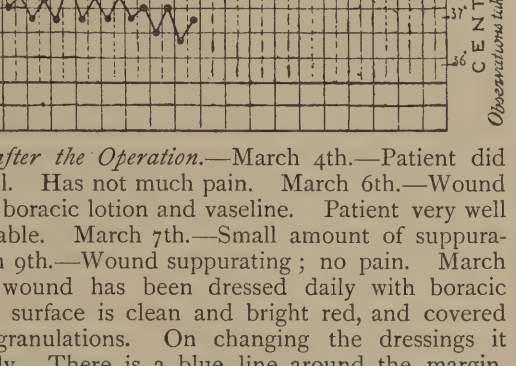


Progress after the Operation.—March 4th.—Patient did not sleep well. Has not much pain. March 6th.—Wound dressed with boracic lotion and vaseline. Patient very well and comfortable. March 7th.—Small amount of suppuration. March 9th.—Wound suppurating; no pain. March 24th.—The wound has been dressed daily with boracic lotion. The surface is clean and bright red, and covered with small granulations. On changing the dressings it bleeds readily. There is a blue line around the margin, especially at the upper part. Patient is well and has no pain. March 26.—Skin grafts were placed on the surface of the wound. March 29.—No signs of skin grafts; surface of wound clean. April 2nd.—Surface of wound clean; blue line round edge. Very little discharge. *Patient made an out-patient*, with orders to dress daily with boracic lotion.

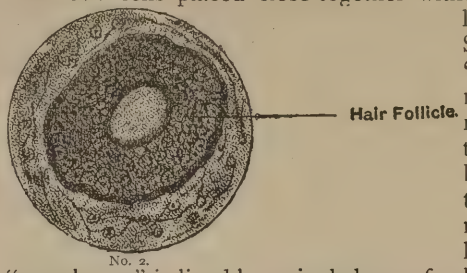
Pathology.—The ulcer measures 3½ inches by 2½ inches. The upper surface has been described clinically. On the under surface and beneath the heaped-up portion were several cysts, from which a quantity of caseous material came away on incision. The whole of the under surface of the part removed was covered by fibrous tissue (temporal fascia).

Recent Microscopical Section.—Stained in logwood and eosin, and mounted in balsam. *Lower Power:* The section was cut from a portion of the upper heaped-up part of the ulcer, and is vertical. Passing from without inwards are seen:—(1) A thin layer of *stratified epithelium* pierced in several places by (2) *hair follicles.* Scattered over the field are (3) *epithelial nests* surrounded by the (4) *ground tissue.* There are also (5) *sebaceous follicles.* (6) *Sweat glands* cut in various directions, and (7) *Hair follicles.*

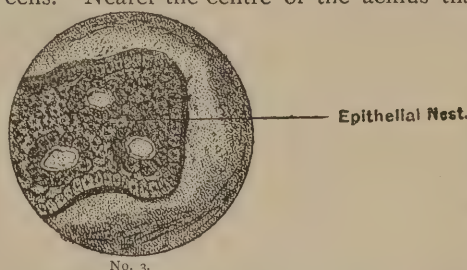
High power.—The above when seen with a high power (Zeiss D) present the following characters:—1. *Stratified Epithelium* (*a*) Granulation cells. (*b*) The deepest layer consists of columnar nucleated epithelial cells. (*c*) Processes pass down into growth. 2. *Hair follicles.*—There is no excessive growth of the epidermic coat of some of the follicles. 3. The *Epithelial nests* are sharply defined from the surrounding ground tissue, and are made up of a number of small oval cells placed close together without any intercellular substance. Surrounding each "nest" is a narrow, highly refractive, structureless membrane, resembling the "glassy membrane" of a hair follicle. This "membrane" is lined by a single layer of columnar nucleated epithelial cells. Scattered about the "nest" are several acini lined by a single layer of columnar nucleated epithelial cells. Nearer the centre of the acinus than the columnar cells, is seen a transparent refractive membrane (cuticle of hair). The centre of the acinus is filled with a structureless material (hair). Filling up the spaces between the acini are numbers of small oval nucleated epithelial cells placed close together. A portion of the "nest" was undergoing fatty degeneration. *From this part of the section it would appear that the epithelial nests were due to an irregular growth of the epithelial cells of the hair follicles.*



No. 1.

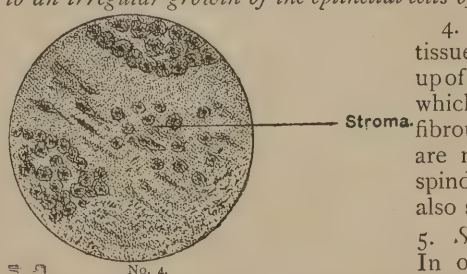


No. 2.



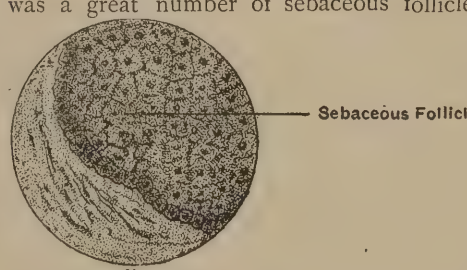
No. 3.

4. The ground tissue (*stroma*) is made up of granulation tissue which is organised as fibrous tissue. There are numbers of both spindle-shaped, and also small round cells.



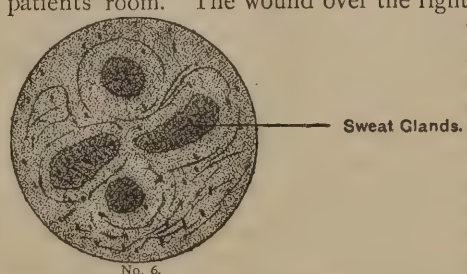
No. 4.

5. *Sebaceous follicles.* In one section there was a great number of sebaceous follicles, the epithelial cells of which appeared to have proliferated to a considerable extent. 6. *Sweat glands*—normal.



No. 5.

April 22nd. Patient was seen in the out-patients' room. The wound over the right temporal region was rapidly healing. The surface was clean and red, and covered with small healthy granulations. The edges were sloping, and the blue line was very well marked. There was no discharge. Patient was in good health.



No. 6.

Remarks.—When seen a year afterwards, the patient remained perfectly well, and may therefore be pronounced cured. The case, so fully and so ably reported by Mr. Althorp, illustrates well the usual history and the pathology of rodent ulcer; and the description of the treatment adopted, exemplifies the method always pursued when the growth (for I think it is clearly made out to be a form of epithelioma, though the two differ materially in clinical characters) can be efficiently cut out; but where this cannot be effected, much can be done by the use of Volkmann's sharp spoon, and the employment of a strong caustic, or the actual cautery. What is necessary, is a very complete removal, leaving only healthy tissues. It is astonishing to see how rapidly a large raw surface will contract and heal. Hence, unless some vital part be in question, I never regard the gap that will be left, "leaving that to be dealt with afterwards," but simply sweep away all the disease, taking care to let the incision be fully one third of an inch beyond the margin of the sore.

THE ANIMAL ALKALOIDS: THEIR PROBABLE ROLE IN FATIGUE AND SLEEP.[1]

A Resumé,

By A. M. BROWN, M.A.

"WHY we sleep?" and "How we sleep?" are questions still awaiting solution. The best informed, as Exner and Beauris, have declared that we know nothing definitely on the subject. More recently, however, new facts have come to light which materially alter the position; in both fatigue and sleep the principal phenomena, at least, may shortly cease to be a mystery. With M. Errerd's work before us, let us see how far this is probable.

The periodical suspension of the activity of the superior nerve-centres is the dominant character of sleep. The attempt to explain it by the condition of the cerebral circulation has often been made; but, by a singular contradiction, some authors set up the intervention of congestion, whilst others insist on anæmia. Recent researches seem decidedly favourable to this latter hypothesis however, in support of which somnolence from great loss of blood, and that kind of sleep that Fleming was able to produce by the compression of the carotids may be cited. The variations of the cerebral circulation present then a certain relation with the alternations of sleep and wakefulness, but as these variations themselves require explanation, they do not suffice for any theory of sleep. The capital importance of oxygen in keeping up the activity of the tissues once recognised, it was very natural to make it play a part in the explanation of sleep, and to attribute it to a less absorption of oxygen—to an anoxia of the brain. This is an idea which goes back to Alexandra von Humboldt, at the end of the last century, and which has been since maintained with certain variations by Purkinje, Pfluger, and others; but this affords no explanation of the cause of the periodicity of normal sleep. Why should the quantity of oxygen received by the brain diminish at certain times and increase at others?

Sleep is not the only phenomenon which returns regularly and in some sort rhythmically in the life of the organism. The movements of respiration and the contractions of the heart are in point. The study of them ought to simplify the problem.

[1] Pourquoi Dormons-Nous? Par M. Leo Errerd, Pofesseur a L'Université Libre de Bruxelles.

It is generally admitted, thanks to the labours of Rosenthal, that the respiratory system is essentially regulated by the richness of the arterial blood in oxygen and carbonic acid. When the blood is charged with oxygen, the nerve-centre which governs respiration, suspending its activity, the tissues take up the oxygen of the blood, replace it by carbonic acid, and thus the blood, become modified, excites the respiratory centre. A respiratory movement then is produced, the provision of oxygen is renewed, the carbonic acid eliminates itself; things restored to their initial condition, the process recommences. It is instability, even in the condition of the blood, which excites the movements necessary to recovery of the primary equilibrium.

The exhaustion of a muscle by labour, and the restoration of its excitability by rest, are phenomena still more comparable with the sensation of fatigue and the restorative effects of sleep. The researches of J. Ranke, which date more than twenty years back, tend to the admission that the exhaustion of the muscle results from the accumulation of substances produced by its contraction, in particular that of lactic acid. If we inject these fatigue substances, as Ranke calls them, into a fresh muscle, it becomes incapable of working—it is exhausted; if we remove them by an artificial washing, or if we allow the circulation of the blood time to carry them away and to replace them by other materials, the fatigue disappears, the muscle acquires again its contractibility, it renews itself. Ranke supposed that fatigue substances operate by monopolising the oxygen to the detriment of the muscle. In any case it would here be still the instability in the chemical condition of the organ—its temporary intoxication—which forces it into a state of rest, until it be disencumbered of the products of its activity, and finds itself in some sort in another condition.

We may ask ourselves whether a theory of toxicity, analogous to those of respiration and of muscular fatigue, would not apply to sleep. Heynsius and Durham assented to this view, then Obersteiner and Binz declared in the same sense. These latter think that the products of exhaustion are continually forming within the brain when active; that their accumulation brings on sleep; and that they are then eliminated by the blood which passes through that organ. But what are these products? From what we know of the reaction of the grey substance and tetanized nerves, Obersteiner was of opinion that it operated essentially as an acid; and such also was the opinion of Heynsius, of Durham, and of Binz. Preyer has expanded this idea, and ingeniously combined it with the theory of sleep by default of oxygen. He arrives also at a conception altogether parallel to that which Ranke had formulated for the muscles. According to Preyer all organic activity gives rise to products of exhaustion, to substances which he calls *ponogenes*—that is to say, engendered by fatigue, from πονος—fatigue, and γενομα—to produce, which accumulate during wakefulness, and, being very oxidizable, terminate by diverting to their profit the oxygen destined to keep up the activity of the different glands, muscles and brain, in such a fashion as that the mental acts and voluntary movements are depressed; the organism falls asleep.

Among the ponogenic substances it is to lactic acid that Preyer ascribes the principal part, and he has made the attempt to demonstrate experimentally that this body introduced into the organism brings on sleep. These experiments have been repeated in different ways. Unfortunately, as Preyer himself has recognized, the results are

not constant, either in the case of man or of animals; thus the theory has not been generally adopted by physiologists.

At the time that Binz and Preyer made known their ideas, we knew of no product of the animal organism similar to the somniferous alkaloids of certain plants. Recent researches have shewn that such do exist, and the question of sleep now naturally presents itself under quite a new light.

Extending to animals, alive and healthy, the researches which Selmi had made on the dead body, Armand Gautier has succeeded in extracting from the flesh of *mammifera* (beef) a series of five organic bases more or less akin to creatin, creatinine, and xanthine. He designates them under the name of *leucomaines* (λευκωρι, white of egg), so as to recall the fact that they are analogous to the cadaveric bases or ptomaines. Pouchet and Bouchard found the alkaloids in the urine of human beings. Gautier himself had indicated it in their saliva in its normal state, and he concluded that animals normally produce alkaloids after the fashion of vegetables. What are the physiological actions of these leucomaines? The aqueous extract of the saliva "is poisonous or narcotic, at least for small birds;" and as to alkaloids from muscular juice, Gautier speaks of them as endowed with an action more or less powerful on the nerve centres, producing somnolence, fatigue, and sometimes vomiting and purging. There is here clearly a question of substances fatiguing and somniferous, such, in one word, as the toxic theory of sleep requires them to be. Curiously, the memoirs of Gautier and their subsequent discussion at the Academié de Médicine, where the importance of leucomaines as regards pathology has been so clearly brought into relief, their signification physiologically seems to have been altogether overlooked, and their probable relation with sleep has not, as far as I know, been mentioned. What was more natural than to bring together the work of Gautier with those above mentioned? The idea was in the air, and was incidentally alluded to by De Parville in a scientific chronicle of the *Journal des Debats*. After having stated the results that Gautier had just obtained, he borrowed of him this phrase: "It is after perfect sleep or rest that the animal is more particularly anærobic and consumes more oxygen than it receives," and he adds, in a note, "during sleep the oxygen absorbed does not correspond to the carbonic acid exhaled. We would be tempted to believe that the excess burns the toxic matters, and that sleep would principally be caused by the accumulation in the blood of leucomaines or analogous substances." It is to be observed that the accumulation of oxygen during sleep, on which De Parville insists, seems to be disproved. Voit expresses himself thus on this subject: "It is in consequence of an error in the arrangement of the experiment that Pettenkofer and myself had concluded at the time that the oxygen is stored up in considerable quantity during the night, and utilised afterwards in the daytime and during labour."

Quite recently Bouchard in his researches on the toxicity of the urine of a healthy human being, has compared the urine secreted during wakefulness and during sleep, and, *en passant*, he makes allusion to the theory of sleep. Without specifying the nature of the poisons with which the question has to do, he says: "The urines of waking and sleeping not only present differences in intensity, they differ also as to quantity. The urines of the sleeping hours are convulsivant, the urines of the waking hours are very little or not at all so; but they are narcotic. It is at this stage that one might ask whether Preyer's toxic theory of sleep should not be accepted. What is certain is, that during wakefulness the body fabricates a substance, which if acccumulated would produce sleep; and that during sleep it elaborates in place of this narcotic substance, a convulsivant substance which, if accumulated, would produce the muscular shock which is provocative of waking. It perhaps might be objected that if the poison which is narcotic brings on sleep by its accumulation in the organism, it is in the tissues and not in the urine that one ought to meet with it during wakefulness. But to express oneself on this point safely, as on many others, it will be well to await the continuation of the labours of Bouchard, and notably the extraction and the dosage of toxic substances. In any case, it appears rational to base a theory of sleep on the products that may be detected in the tissues even of the organism rather than upon those which it eliminates by its secretions.

According to a profound remark of Claude Bernard, all vital manifestation is connected with the destruction of organic matter. This is a consequence of the great principle of the conservation of force. A muscle contracts, when sensibility, will, and thought manifest themselves, when a gland secretes, the substance of the muscle, of the nerves and of the brain and glands, becomes disorganised, destroys and consumes itself. In a certain sense life is thus but a prolonged partial suicide, to use an expression which Peter recently made use of.

If it be a commonplace to say that to labour, the living being must burn organic matter as the steam engine burns coke or coal, it is clear that in the one case as in the other, waste, ashes, and ponogenes ought incessantly to produce themselves. No more in the living machine than in the other can these ashes accumulate without inconvenience, as they tend to the detriment of the tissues in taking the place which the new utilised elements ought to occupy. But there is more than this, the cellular scoria is probably injurious in another way. Besides positively encumbering, they may in their turn act on the vital phenomena.

We have no difficulty, then, in conceiving that the animal machine cannot continue to work if it does not disencumber itself of its waste and its ashes, and if it does not procure fresh combustibles; the elimination of ponogenes and organic reparation appear to us as the indispensable corollaries of work. It is possible, especially when the activity is intense, that these two functions may be accomplished less quickly than the inverse phenomena, and the organism invaded at the end of a certain time by its overwaste may find itself incapable of continuing to work until it can be purified by rest. And here, to begin with one cause of alternations more or less regular, we foresee that phases of activity and repose must necessarily in turn succeed each other. It is, moreover, no other than a manifestation of the character which discovers itself in all movement: rhythm.

But if general considerations permit us to understand the necessity of repose, they are insufficient to explain to us the mechanism of sleep. This phenomenon signifies something more than the functional incapacity. It is eminently a question of a nervous order. All cellular waste, every ponogenic body is not actively somniferous. It requires for that: (1) That this body should operate in a special manner upon the superior nerve cells; (2) That it suspend this activity for a time.

Do we know any substances possessing these properties? Undoubtedly; ether, chloroform, hydrate of chloral, and in eminent degree the alkaloids which are narcotic: morphia, narcein, etc.

And if now we pass in review the products fabricated by the organism, there is certainly none of them which will better satisfy us than the leucomaines under the conditions which we have just theoretically indicated.

The study of the leucomaines is scarcely as yet begun, but an analogy which seems interesting is already evident. According to Gautier, the great part of the leucomaines, as well as of the ptomaines are very oxidizable, and morphia is precisely that which makes itself observed by reason of its great oxidizability. Bettink and Van Dissel assure us also, that out of forty-two vegetable alkaloids tested by them, morphia alone divides with the ptomaines the property of forming Prussian blue, by reduction of the perchloride of iron and ferricyanide, and that notwithstanding the presence of an oxidant so powerful as chromic anhydride.

It may be asked, in what way do leucomaines act upon the nerve cells. Is it directly or indirectly in the taking up of oxygen, as Preyer supposed, as regards his ponogenes? It would be premature to wish to settle definitely the question, but in the actual state of the question the first hypothesis appears much the more probable. If we take as terms of comparison the vegetable alkaloids, no one will be likely to suppose that morphia brings on sleep by the subtraction of oxygen; for one centigramme of a salt of morphia, a sufficient quantity of itself to cause sleep, does not require for its complete oxidation more than two centigrammes of oxygen—say, less than the eightieth of what we inhale every minute. Again, we do not know what quantity of each leucomaine is necessary to occasion fatigue and somnolence, of which Gautier speaks, but the quantity is certainly small. The moment, moreover, one comes to think how little abundant the leucomaines are in the normal organism, it becomes difficult, if not impossible, to attribute sleep to the privation of oxygen, which may result from their oxidation. Another fact also makes against the theory of sleep by anoxia, it is that many oxidants—halogenium, ozone, oxygenised water —are narcotic. There are, on the contrary, good reasons in favour of a direct action of leucomaines on the brain. Rossbach has seen that many vegetable alkaloids, morphia, quinine, atropia, veratria, strychnine, modify the albuminoidal matters, such as the white of egg, the serum of the blood, the muscular juice, and that by augmenting their coagulability, the albuminoidal precipitate thus obtained preserves always a certain quantity of alkaloid even after prolonged washing. This precipitate excercises no coagulating action upon the white of egg when dissolved, and Rossbach thence concludes that the alkaloids must be in chemical combination with the precipitated albuminoidal matter. Binz tells us that soporifics, such as morphia, chloral, chloroform, and ether put into contact with the grey substance, renders it morbid. This is the sign of a species of coagulation which other non-soporific bodies would not occasion: atropine, caseine, chlorox-alethylin, camphor, pyrogallic acid. Claude Bernard was also of opinion, at least as regards ether, that anæsthesia is caused by a sort of coagulation. Let us observe that muscular fatigue could no longer be attributed, as Ranke thought, to a monopolizing of the oxygen by the products of contraction, but much rather to a direct influence of the acids formed; for the phosphate acid of soda, which is not oxidizable, absolutely "fatigues" the muscle just as lactic acid does. Leucomaines might, again, act indirectly in another manner by modifying the cerebral circulation. It is an hypothesis which has already been put forth to explain the action of narcotics, and in this way the vaso-motor theory of sleep is arrived at. But such opinion seems contradicted by the direct observations of Binz. Upon a dog and rabbits when trepanned, he saw that anæmia of the cerebral surface only supervened slowly in the complete state of sleep. "Anæmia is then in this case a consequence of sleep, and not sleep the consequence of anæmia." The author adds, after having recalled the case of the alimentary canal, which is pale and bloodless during a state of fasting, and filled abundantly with blood during digestion: "Cerebral anæmia in prolonged narcosis is in harmony with this general rule, that the flow of blood towards the organs diminishes when they are at rest."

The influence of ponogenes may then probably be summed up in these terms: not anoxia, not anæmia, but direct intoxication. A theory of sleep ought to account for the normal linking together of these three things: work, fatigue, and sleep. It is easy to see that the toxic theory satisfies this condition. All work, whether it be muscular or cerebral, engenders loss of material. This by deterioration renders the continuation of labour painful: this is fatigue. Finally, the waste debris, and notably the leucomaines, finish by intoxicating the superior nerve centres (as morphia would) to the extent of inaction: this is sleep. There we have the phenomena reduced to their most simple expression. But a mass of accessory circumstances arise to complicate the consideration of the question. The most important it is necessary to note. First of all the living being struggles incessantly against this intoxication by which he is menaced. It seeks to disencumber itself of its refuse material; the circulation drains them off; respiration and secretions expel them; the liver, it seems, arrests or destroys one portion of them. And the more intense the labour is the more do all these functions become active: the circulation increases, washing and cleansing the organs; the respiration, accelerated, eliminates more carbonic acid; the emission of urine is often augmented; perspiration makes its appearance, refreshing the organism, and taking away from it, moreover, a small quantity of refuse products, such as urea and creatin. These multiple depurations enable the organism to maintain activity for a certain time, but not indefinitely. Why so?

If, by an excess of work, certain of our organs have destroyed all their utilizable materials, and are encumbered by ponogenes, it is clear that these organs are, until a new order, incapable of working again. But we do not arrive under the ordinary conditions at this extreme degree of exhaustion, and it is even doubtful whether we ever do arrive at it. It is a fact that the sensation of fatigue has already become invincible, before the physical, the real fatigue, has attained its ultimate or extreme limits. The ponogenes operate, not only upon these organs where they have begun their existence, but even upon the nervous extremities which border on these organs and upon the centre themselves. To this triple influence of the ponogenes three significations of the word "fatigue" correspond. In effect, there is room to distinguish between the true fatigue of the muscular fibres of the arm, for example, which is measured by the diminution of their excitability, the fatigue which is subjective, which we feel locally in this arm; and

the general sensation of fatigue lassitude which explains itself by the desire of sleeping. After having lifted for some time a weight, we may experience an intense fatigue in the arm, but no need of sleep, whilst we may fall, as they say, asleep, without experiencing any considerable local fatigue. Of these two sensations, one is peripheric, the other is central. It is this latter which interests us the most, and it is its genesis that it behoves us to study most clearly.

Cerebral activity, such as manifests itself during the state of wakefulness, is connected with reactions of a chemical nature, with discharges which occur in this eminently explosive matter of the protoplasm of the nerve-cells, and the gray cortex. Now, among the ponogenes constantly engendered within the different organs which are in operation, we know that there are narcotic compounds, comparable to alkaloids. In all probability these bodies have a particular affinity for the nervous cortical cellule; in any case they act upon it, they modify it, they fix themselves there more or less steadfastly. Their elimination by the enunctories, as already mentioned, will never be other than partial; whilst one portion will be drained by the secretions, another will possibly be undergoing destruction by oxidation, a third will be retained within the brain. It is believed that the nerve centres, thus modified, perform with less and less facility their function of explosion, and it will require excitements more and more vigorous to maintain the condition of wakefulness; after a certain stage our movments become tardy, our sensations become blunted, our thoughts are clogged, in a word, we feel ourselves fatigued. There comes at length a movement in which the ordinary excitements are no longer sufficient to permit the explosion of the cerebral protoplasm, its activity is provisionally suspended; we sleep. By this theory, it is obvious that the ponogenes only operate on those of the nerve-cells into which they penetrate. This localised action explains to us what we may call "partial slumbers." The profoundest sleep, says Exner, with reason, is connected with insensible transitions with perfect wakefulness. If one is very circumspect whilst falling asleep, it may be remarked that the circle of ideas with which one is occupied is more and more contracted. We can say that certain groups of ideas still are wakeful, whilst that others are already subject to sleep. The cells of the organism fall asleep one by one, even as they die one by one, following a hierarchical order. Whilst admitting a great latitude for the intervention of accessory causes, we foresee, nevertheless, that the most elevated of the centres are in general the first to become drowsy, then sleep overtakes by degrees the inferior centres.

These remarks explain in a certain measure the phenomena of somnambulism; for Jean Müller has already shown that the question there is one of partial sleep. On the other hand, certain superior centres, the first asleep, are capable of awaking themselves separately or in groups. Perhaps one may come by this means to understand the variety and the want of connection in dreams, and painful nightmares, during which we endeavour to perform a movement, and feel ourselves restrained: here the motive centres would be asleep, whilst certain intellectual centres would be awake. In somnambulism, on the contrary, it would be the motive centres which were awakened, and the intellectual centres that continued asleep. Contrary to Preyer, Errard is led to regard the somniferous action of the ponogenes as direct, and not as the indirect result of a subtraction of oxygen. The reasons have been stated. However, the oxidizability of the leucomaines should also to be taken into account, and in place of being the cause of sleep, it explains according to this view the cessation of it.

If the accumulation of a certain quantity of leucomaines within the ganglionary cells brings on fatigue—then sleep, sound and refreshing, which accompanies it, must be due to the disappearance of the leucomaines. Have they been simply removed by the circulation, or are they destroyed? Both factors might intervene; but since it is probable that the leucomaines are chemically retained in the cerebral nerves, as were the alkaloids in the experiments of Rossbach, the mere blood-washing would not remove them except with difficulty; and since from other sources we have a knowledge that they are oxidizable, it is natural to think that the oxygen whose oxidizing power still being exercised in the living organism, attacks them and burns them little by little. Does this only take place during sleep? There is no reason for thinking so. The accumulations of leucomaines during the state of wakefulness does not prove that their production is suspended. It signifies only that the production is then in excess of the oxidation and elimination united, which is only very plausible. During the condition of waking, the activity of the organs continually engenders new quantities of them; during sleep the production is, if any at all, at least very much reduced, for the muscles are in repose, the pulsation becomes lessened, many secretions are diminished, respiration is diminished, the brain is out of gear. Now, the normal adult taking as near as may be about eight hours of sleep as against sixteen of waking, we might conclude that the ponogenes are formed on an average, during waking, one and a half sooner than they oxidize and eliminate themselves. It is useless to add that here a mass of factors are overlooked, and that this figure represents only a crude approximation. As there is no reason to admit that the products of oxidation of the leucomaines can have, like them, a special affinity for the protoplasm of the grey substance, we conceive their being immediately swept away in the circulatory current. The nerve-cell therefore is cleansed, it becomes again accessible to impressions from without, and a slight exciting cause suffices to bring about waking. But this is not the whole. Sleep does not consist alone in the elimination of ponogenic matter. That is only one phase of things, and we have already said that we must regard also the organic reparation. Side by side with the cleansing there is the reparation. When once the leucomaines have invaded and paralysed the cortical cells, all the organism is relieved of the tyranny of the brain, and each tissue is capable of restoring itself tranquilly by inmost nutrition. Thus we understand that one rises up in the morning, not only freed from his fatigue, but again armed with strength for new activity, and that sleep, even when artificial, may be beneficial. "He who sleeps, dines." As regards the amount, the quantity of leucomaines contained in the organism is doubtless subject to continual variations; it increases or lessens according as the productive phenomena of the dissimilation preponderate. We see, then, that an increase of work may be capable of leading to a decrease of fatigue, if this work increases at the same time and in a stronger proportion, the oxidation and expulsion of the waste. Perhaps there we have one of the causes why exercise in the open air is so healthy. At other times the decrease of fatigue is only apparent. In proportion as a great weariness takes hold upon, as the cells which intervene in conscious perception

terminate by being exhausted in their turn, consciousness becomes more and more obscure, and fatigue in so far as regards the sensation experienced by the patient may diminish thus, because of the excess even of work. It may happen, as regards an opposite cause, that the beginning of rest, far from resting us, augments the subjective fatigue. But this kind of phenomena recognizes another explanation, about which we shall say a few words.

In the present day it is scarcely to be doubted that certain chemical decompositions of the molecules of the nervous protoplasm are the condition of cerebral activity. From all that precedes we are led to attribute sleep also to a chemical reaction between this protoplasm and the leucomaines. Now in virtue of principles of mechanics, it is in general more difficult to impress on a body a determinate form of vibrations when it is already vibrating. Without quitting the domain of physiological chemistry, Nageli has shown that the existence of fermentation hinders more or less completely a different fermentation from establishing itself in the same medium. If we apply the like idea to the ganglionary cells, a mass of facts which are familiar to us become at once intelligible. In normal life we are conscious of no fatigue during the greater portion of the day, because the cerebral protoplasm defends itself against the ponogenes by its very activity, and it is only towards evening, when the army of the ponogenes is become more formidable, that the nerve centres commence to become feeble. One may up to a certain point struggle against fatigue, or betake oneself to repose; the vigorous and varied sort of excitements retard sleep, whilst tranquility, monotony, inaction, *ennui*, and silence are favourable to it. Immediately that the nerve-cells give way before the enemy, they lessen their activity, the leucomaines invade them with more and more facility; first fatigue, then sleep, supervenes. Fatigue appears to us, from this point of view, like a conflict between the activity of the protoplasm and the invasion of the waste matter; and sleep is the temporary victory of the waste matter over the protoplasm.

These observations give the key to a phenomenon that, at first sight, might seem to be opposed to our theory, and it is this:—Although the formation of narcotic substances goes on all day, the passage from wakefulness to sleep is usually rapid enough. Our day of work has but little twilight.

This leads us to a delicate question, and one which as yet is very little studied—the soundness of sleep. Let us try to enter upon it. In our theory the soundness of sleep must be in proportion, at every moment, to the number of the molecules of the cortical centres, which are in combination with the leucomaines. At the beginning of sleep, everything facilitates the arrival of the leucomaines; they are relatively in abundance in the organism, and the central cells being inactive, leaves them free entry. Thus sleep becomes soon more and more profound, soon the maximum is attained, and all the stock of leucomaines is combined. But during this time the destruction and the elimination of leucomaines have continued going on more actively in proportion as the grey substance appeared to be a favourable medium of oxidation; a portion then of the leucomaines will be constantly destroyed within the brain, and the intensity of the sleep will not take long to decrease, but that with a decreasing rapidity, seeing that oxidation takes place on less and still less quantities of leucomaines.

Experiment agrees very satisfactorily with these deductions. Kohlschutter determined, from half-hour to half-hour, the soundness of sleep in the case of the same individual, in accordance with the intensity of sound necessary to excite the awakening. In spite of the sources of error in a similar proceeding, the following results might, according to Exner, be regarded as established. The intensity of sleep increases promptly during the first hour; then it decreases, at first in a rather rapid fashion, and then more and more slowly until the awaking up. Kohlschutter has given us a curve which indicates these variations; a thing of some interest, and, as we may foresee, the form of this curve remains the same, whatever may be the intensity of the sleep absolutely. It applies as well to sleep produced by a slight degree of alcoholic intoxication as to normal sleep.

In forming a suitable hypothesis as to the proportion of leucomaines which are being continually oxidized our theory would furnish a curve of the same kind.

An observation of Brever, which it is easy for one to repeat on himself, deserves here to be mentioned. We often go to sleep whilst passing through oscillations of consciousness and of unconsciousness more or less distinct. The fact seems sufficiently explicable. At the precise moment at which we lose consciousness of what surrounds us, the least diminution in the flow of the leucomaines towards the brain may permit the protoplasm to escape sufficiently their action for consciousness to return; but, the flow again augmented, consciousness vanishes anew, and so continues until the reign of sleep be definitely established.

If this theory of sleep be correct, it may be asked whether there may not be counter-poisons, antidotes of our ponogenes which are soporific—ponolytes, if you will—which might counteract the fatiguing action of the products of activity. Why not? Grutzner and Gscheidlen have established that remedial substances are formed inside of the muscle by the effect of contraction; and reciprocally, it appears, according to Kronecker, that the oxidants, such as the permanganate of potash, in very feeble solution, returns to the fatigued muscle its excitability and strength. We likewise know that the leucomaines are oxidizable, and it is probable that one might destroy them by means of oxidants. Yawning, that deep inspiration of the tired man, might its purpose not be that of furnishing him with a precise increase of oxygen?

But, besides the oxidants, it might be possible to discover veritable antidotes to the narcotic leucomaines. For example, alkaloids antagonistic to these substances, as atropine is antagonistic to pilocarpine; coffee, which wakes up the brain; coca, which suppresses, they say, during several days, hunger and fatigue, are perhaps of the number. We must frankly add, however, that if a pharmaceutic product happen to eliminate fatigue artificially, that does not imply that it procures by the same time organic restoration—the restorative effect of a good sleep.

It would be well to guard against explaining too many things by alkaloids, and, according to the saying of Guerin, "after having abused the microbes let us endeavour to avoid abusing the ptomaines." But it is just to remark that if Selmi has seen all the importance of animals, alkaloids, as regards forensic medicine, if Gautier, Bouchard, and others have indicated their *rôle* in the genesis of diseases, their important place in normal physiology still remains, to a larger extent, a virgin study, and one which promises fresh harvests in discoveries. Already we catch a sort of glimpse

that inebriation from work, inebriation from success, inebriation from love, might well cease to be mere metaphors, and range themselves with the action of different toxics upon our nerve centres. Errard hopes to have shown the probability that fatigue is, in the proper sense of the word, an intoxication, of which sleep is the normal antidote. Who knows whether many physiological acts (respiration, movements of the heart, micturition, defecation) may not be like sleep dependent on specific bodies, acting, be it on the nerve-centres or upon the peripheral organs? Organic rhythm would be due to the fact that a given physiological act engenders substances, which tend to provoke the contrary act, just as the descent of the pendulum provides the necessary power to cause it to rise again. A very recent work by Zuntz and Geppert concludes that over and above the holder of the blood in oxygen and in carbonic acid, there is yet a particular and unknown substance produced, and chiefly by the muscular activity, which normally intervenes to regulate the respiratory movements.

Errard, in conclusion, sums up the theory of sleep into a few lines: "The activity of all the tissues and in the first line of the two most active, which are the nervous tissues and the muscular tissues engenders bodies more or less analogous to alkaloids, the leucomaines. These leucomaines are productive of fatigue, and are narcotic. These leucomaines, then, must at length occasion fatigue, and bring on sleep. On awaking, if the organism be in a state of repose, it is because these bodies have disappeared. Therefore, in that case, they are destroyed and eliminated during normal sleep, the restorer." All this appears logically indisputable; but it pertains to direct experiment to furnish the proofs where we as yet have only arguments. The quantity of leucomaines, their presence in the brain, the more complete study of their physiological properties are the first problems which will offer themselves for solution.

It may be asked whether the leucomaines of Gautier have so close an affinity to the ptomaines and the alkaloids, properly so-called, as that author asserts. There is here a question of degree which admits of difference of opinion. What appears to be established by his researches, is the very general formation of organic alkaloids in living beings, many of which possess narcotic properties. There we have all that is necessary to serve as a starting-point for the toxic theory of sleep, such as we understand it.

EXPLANATORY NOTES TO DR. KEYES' INVESTIGATION OF ELECTROLYSIS.

By C. R. Dickson, M.D., Kingston (Ont.), Canada.

[Communicated by Dr. Steavenson; received by him from Dr. Robert Newman, of New York.]

In the issue of this journal of November last, appeared an abstract of a paper read before the American Association of Genito-urinary Surgeons, at its second annual meeting, entitled "The Curability of Urethral Stricture by Electricity —An Investigation;" by E. L. Keyes, M.D. I was glad that the paper appeared, as it will serve to demonstrate that electricity may fail even in the hands of one of the most skilled of genito-urinary surgeons, for most certainly that is all that it proves. When a few more such results shall have been given to the expectant profession, the fact will at last dawn upon it that electricity is not the simple, harmless panacea that many of its advocates would have us believe; but on the contrary requires in its successful application, rare tact, judgment, and skill, combined with a mature acquaintance with its fundimental laws, such as is gained only by plodding, earnest, patient study of it in all its forms, and by experiment in which common sense and physiology have a hearing (for instance he should not expect the aorta of a dead sheep placed upon a piece of beef to play the rôle of an urethral stricture in the living man, as was quite recently reported).

Having made this discovery—too late, alas, in many cases —the general practitioner as well as specialist, be he genital, or urinary, or both, or neither, will, if wise, do one of two things, either settle down to study, or which is the better or at least safer method—let electricity severely alone, and send suitable cases to be treated by those who already understand the subject and are known to be successful in the treatment of such cases. To the student, as yet unprejudiced, belongs the golden opportunity, let him insist on practical instruction on the subject by competent teachers, and any labour he may expend on this most attractive branch of therapeutics and surgery will be amply rewarded, and he at least will appreciate and quite understand the removal of adventitious material by sloughing and by absorption. But I wish to call attention to the rather unfair use of cases 8 and 9; the criticism of the remainder of the article, I leave to others should they consider it worth their time.

While in New York a short time ago on electrical business, my friend, Dr. Robert Newman, kindly permitted me to see Dr. Keyes' letter to him in reference to case 8, J. D., and copies of his replies, all of which I read carefully and noted, and now propose to give the gist of. Neither of us had seen the complete paper at that time but only a synopsis of it in the "*Medical Record*."

On January 10th, 1888, Dr. Keyes writes that he is much interested by Dr. Newman's report; expresses a desire to investigate; asks for information to his assistant; and as to where Dr. Newman's electrodes could be obtained. Later, January 21st, he mentions the Mallez-Tripier incident—or more correctly accident—says he is incredulous, but "whatever the result may be I shall give it to the world without fear, simply stating what I conclude after properly investigating," stating that he has instruments ready, and some dispensary cases. He proposes to send one case to Dr. Newman, having first examined, and will examine it again *after Dr. Newman pronounces it cured*, if allowed (italics mine). Then J. D. is sent with Dr. Keyes' assistant, and Dr. Newman having stated that the case is not a favourable one on account of a previous surgical interference, Dr. Keyes writes on February 6th: "Dont let us go on with the D—— case unless you are willing to abide by the result;" and offers to "look up another case," to which Dr. Newman replies on the 8th: "I do not understand what you mean by saying I should be willing to abide by the D—— case. I am sure the D—— case will come out all right if the man does what I tell him." "But I attend the D—— case for your pleasure, and not as an investigation; on the other hand I can refer you to many physicians who have seen patients before electrolysis, and examined years after cure and found that no relapse had taken place." But that would be foreign to an *investigation*. On February 20th, Dr. Keyes repeats his question, "I ask you (and still ask) whether you are willing to accept D—— as a test case, etc.," and on the same day

Dr. Newman answered, "I expect that electrolysis will cure the stricture of D—— even if the case were worse. But I cannot agree to have this *one* patient put up as a test case, when I have hundreds to show and can verify the results 'without relapse,' by reliable physicians who have examined and re-examined these patients." Dr. Newman also expressed a readiness to call on Dr. Keyes and give proofs and statistics. A report having been asked for on June 26th, as Dr. Keyes is about to sail for Europe, Dr. Newman replies two days later, "I take pleasure to state the present state of D—— whom you sent to me for treatment for, as you expressed it, 'double linear stricture at $4\frac{1}{2}$ inches.' At the present time this stricture has entirely disappeared. Nevertheless, the patient is not well, or cured. I found on examination when D—— first came to me, a second stricture at $5\frac{1}{4}$ inches from the meatus, as also contracture of the bladder which propelled the sound, and sometimes caused such spasm that no instrument would pass beyond six inches. There is much irritation and discharge of mucus, pus and blood from the urethra. This second stricture is improved, so that No. 25, Fr. will pass, but the ring constricting the stricture can be felt distinctly, and is not cured at the present time. For the spasm of the bladder he has not received any treatment, and the galvanic current will certainly never cure spasmodic action of the bladder and urethra. I now propose to treat D—— for the latter trouble during the hot season, taking time and report to you later *in extenso*." But this would not suit the *investigation* either, as Dr. Keyes hastens to say on July 23rd: "Will you allow me to ask you not to give D—— any further treatment, that I may have an opportunity to examine him again in the autumn, in order to determine his ultimate condition." To this Dr. Newman naturally objects on July 28th. "I wish to call your attention again to my former letter of 28th of June, in which I said that the case is not cured, and again, that I did not treat the case with its complications but only the stricture as desired. And further, as I have not the patient under my sole control, even did not know his residence or whereabouts, the result is not as favourable nor cured as I desired to see it. Please take such circumstances into consideration."

On Sept. 4th, Dr. Keyes writes that he has just returned, and proposes to say all he knows about electrolysis in stricture at Washington Congress, and after examining D—— will add that to the paper, and on the 15th continues, "I have examined D—— and find recontraction of stricture being at $4\frac{1}{2}$ inches. I cannot find that any improvement has followed the use of electricity, and on close questioning I learn that his stricture area never has been cut (as he allowed me to suppose) but that the cutting had been a meatotomy. Under these circumstances I see no escape from reporting the case as a failure!!! it seems to me to demonstrate that electricity has signally failed in removing organic stricture in this case."

The last communication is Dr. Newman's reply of Sept. 15th. "In your favour received yesterday you say that the D—— case is a proof of failure of electrolysis, and that you will report it as such. I certainly will, and must protest against such an action as very unfair, as I did already on my visit to you. I have very good reasons for my protest, among which is, D—— was not dismissed by me as cured, but on the contrary withdrawn by you, and thereby any probability of a cure prevented. I am so certain of the efficacy of electrolysis in urethral stricture, that for public good I am ready to demonstrate the success at anytime if such trial is conducted impartially and in good faith." This certainly seems fair enough, and speaks for itself, requiring no comment.

At the personal interview alluded to, Dr. Newman tells me he also objected to case 9, E.S.E. being reported, as Dr. Keyes knew that the patient was badly treated by a physician in Brooklyn, who used electricity in a wrong manner. Later E came to Dr. Newman who refused to treat him; on the patient asking for the direction of a respectable surgeon, if Dr. Newman did not wish to treat him, he was sent to Dr. Keyes.

But Dr. Keyes' plan cannot be interfered with, he cannot well re-write his paper he tells Dr. Newman, but may state verbally that he has seen him. The chance of having a fling at electrolysis is too good a one to miss, and Dr. Newman's many friends at home and abroad must have the news brought back to them that the "Apostle of the Creed" is an impostor, that they themselves have been dreaming, their confidence "due either to the combined credulity of the patient and imagination of the surgeon, or to some special but fortuitous act of Providence, upon the co-operation of which in the case of his own patients, the general practitioner cannot with any confidence rely." And thus the benefactor of his deluded brethren recalls the foolish ones from the hypnotism under which the wicked Dr. Newman has laid them, and if they have not already done so, they will at once read the article recommended by Dr. Keyes in the July and August numbers of the Journal of his speciality, then will turn back to the editorial in the *New England Medical Monthly* for December, 1887, to remind them of how many like themselves thought all along that they had been curing strictures when they really were quite mistaken. Further, our papers will be filled with recantations from Drs. J. H. Kelley, of Battle Creek, J. H. Burchard, of New York, J. J. Berry, Portsmouth, N.H., and a host of others. Of course Dr. Newman is too hardened, no hope for him, he will doubtless remain an outcast from the realms of orthodox surgery of the urethra. But across the pond, F. Swinford Edwards, F.R.C.S., London, will doubtless hasten to inform us that his communication in the *Medical Press and Circular* of April 11th, 1888, was misleading, and all his favourable cases have relapsed since reporting. And the foolhardy practitioner who asks for urethral electrodes at the instrument dealer's, will be withered with a glance of scorn, referred to a museum, and offered an improved urethrotome, on three months' trial and easy payments, with a liberal discount for cash.

But joking aside—for stricture is no joke—why not have the demonstration offered by Dr. Newman? Its success or failure would do more than anything else—including investigations—to fix the status and scope of electricity in urethral troubles, and save a great deal of valuable time and printer's ink, only taking care to first agree on three points:—

1. What constitutes a normal urethra?
2. What constitutes a stricture? and
3. What constitutes a cure?

It is not greatly to our credit as a progressive profession that, while in the commercial world such advantage has been taken of the rapid strides of electricity as a science with fixed laws, so many of our members look upon it with discredit, and call its advocates "cranks," or perchance try it only to fail.

PARTIAL EXCISION OF HUGE LYMPHANGIOMA OF LEG.

By Robert Jones,

HONORARY SURGEON, LIVERPOOL STANLEY HOSPITAL.

This patient was sent to me in April, 1886. She was then twenty-seven years old; had been married six years, and had two children. She was prevented from walking by an immense tumour, extending from the lower and back part of the thigh to the heel. When she stood it rested on the ground; when she moved it trailed after her.

The growth presented the following clinical characters:—In the widest part, about four inches below the knee, it measured forty-three inches; the narrowest part, just above the malleoli, it measured nineteen inches. It presented a brawny varicose skin, involving five-sixths of the circumference of the limb, so that only a narrow strip of healthy skin remained in front of the tibia, patella, and quadriceps. The colour varied from a cholocate tinge to glistening white stripes, due to distended skin. On grasping the mass a brawny sensation, similar to thrombosed veins, was elicited. Here and there one noted a soft cavernous feeling as if fluid were pressed from one cavity to another, and in places there existed distinct fluctuation. A white fluid exuded from an ulcerated patch situated

FIG. 1.

opposite the tendo-Achilles. Patient had probably been affected for, at least, seventeen years. Her mother, when bathing her, noticed that one leg was thicker than the other, but did not remember noting any surface change. There was no family history bearing upon the case, the stock being purely English. At the age of twenty-four the tumour was extremely painful, becoming more so with each suceeding year, until, to use her own phrase, "life became a burden" to her.

The question of treatment was an interesting one. Complete excision was out of the question, because of the absence of healthy skin. I favoured partial excision in the belief that (*a*) the growth would be arrested; (*b*) that the immediate mechanical discomfort would be removed; and (*c*) that the ulcerated patch would cease to trouble. Other surgeons, however, strongly favoured amputation through the thigh, on the ground that (1) a partial excision was patchy; (2) that the risk from hæmorrhage would be alarming; and (3) that flaps necessarily composed of implicated structure would fail to unite. This last reason, which seemed the most plausible, was discountenanced by two facts which I noticed elsewhere—viz., that in spontaneous fracture, due to malignant disease, the bones re-united; and in a case of epithelioma of face, where I performed a partial excision, early union of the malignant flaps occurred. Regarding amputation, the patient was even more decided than I was.

There was nothing remarkable about the operation, excepting very alarming bleeding, thirty or forty large arteries being cut through, which were however speedily secured. The naked-eye appearance of the mass, which weighed five pounds four ounces, consisted in a glistening whitish surface, plentifully dotted with minute loculi, out of which lymph could be compressed. The subsequent progress has been highly satisfactory. In a week the wound was united, with the exception of troublesome corners at top and bottom, which persisted for many weeks. The temperature never quite reached 101, and after the ninth day was normal. She has no pain now; can do any amount of work; does not complain of fatigue; and walks without a limp. Although it is now nearly three years since the operation, the leg has not started to increase in size.

Dr. Barron has kindly supplied me with the following aspect of its microscopic characters, as shown in fig. 2. "The

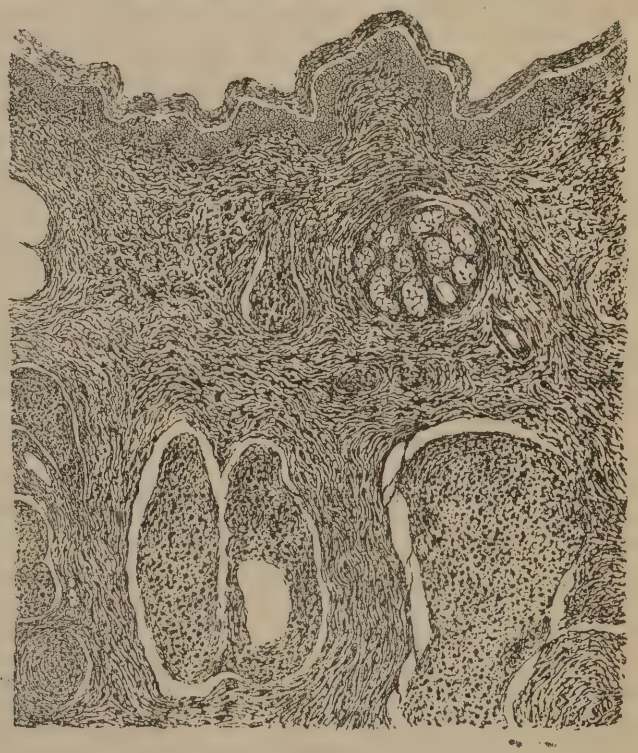


FIG. 2.

skin forming the surface of the tumour is thickened, and the cells of the rete appear large and swollen. The hairs are hypertrophied, and the sweat glands somewhat enlarged and elongated. Both the skin and subcutaneous tissues are full of dilated and somewhat sacculated lymphatics, many of which are blocked by organising thrombi. In some places this process appears to have gone on to the final production of a juicy connective tissue, rich in cells and infiltrated with leucocytes. The process appears to advance chiefly by the formation of lymph clots in the vessel subsequent to organisation."

AN ENQUIRY INTO THE CURRENT THEORIES OF THE CAUSES AND NATURE OF ACUTE RHEUMATISM, AND THE TREATMENT GENERALLY ADOPTED FOR ITS CURE.

By ALEXANDER HARKIN, M.D., F.R.C.S.,
CONSULTING PHYSICIAN MATER INFIRMORUM HOSPITAL, BELFAST.

IT may be stated with safety, and even advanced as a truism, that in the study of disease in general, and of acute rheumatism in particular, it is of the highest importance to have a clear conception of the causes, proximate or remote, which may give rise to the cycle of morbid phenomena known by that name; as, upon this estimate, whether well or illfounded, will materially depend the indications for treatment of the special disorder.

It is indeed a subject of regret, that the theories prevalent regarding the etiology and pathology of rheumatic fever should be characterised by so much inexactness and uncertainty; the dicta of our leading authorities are too often contradictory and misleading. What is regarded to-day as an exploded hypothesis, is frequently accepted on the morrow as a theory beyond cavil; while some writers of eminence and position do not hesitate to avow that, although based on observations of comparatively trivial importance and limited extent, they willingly accept as orthodox, a previously discarded, theory of causation. Although, indeed, it is the undoubted privilege of every student of medical science to speculate freely on the intimate nature and relations of functional or organic disease, and to formulate to his satisfaction a rational hypothesis in accordance with his observation; it may be well for all of us to profit by the prudent maxim of Haynes Walshe: "That false theory must be worse than no theory at all in a sphere of knowledge where speculation entails action, where the practice of an art flows from the doctrine of a science;"[1] and thus the wise practitioner might often be justified in preferring the guidance of an enlightened empiricism rather than the suggestions of an hypothesis however attractive or conclusive it might appear.

While the current of medical opinion has for many years set strongly in the direction of solidism, or the localisation of disease, as opposed to the humoral pathology, and in more recent days in that of the neurotic origin of most disorders, acute rheumatism included; yet, a large number of theorists, in the words of Senator,[2] "look for the noxious principle (of polyarthritis) in some alteration of the blood and humours, more especially the abnormal development of an acid, and lactic acid has actually been specified as the cause of the morbid phenomena; while another class, with Pfeuffer and Hueter, regard endocarditis as the primary change, and articular disorder as a consequence resulting from embolism, by particles of extreme minuteness being washed off from the endocardium of the left ventricle." Some writers uphold the doctrine of the malarial or miasmatic; others the germ theory of causation; the infective and the nervous have also their advocates, who attribute to the effects of a chill the initial disturbance of the system, followed by fever, pain, and arthritic disorder, through the agency of the vaso-motor and trophic nerves, with the possible entrance of micrococci into the blood.

[1] My own theory is that acute rheumatism is essentially a specific form of endocarditis, of neuropathic origin generally allied with myocarditis; that in its unchecked progress it speedily modifies the composition of the blood, the innervation and calorification of the body, in its ordinary course giving rise to lesions in the textures, the joints, the pericardium, the pleura, the neurilemma, the meninges of the brain, in fine, in any organ accessible to nervous or arterial influence. I consider the exciting cause be a chill, and that the morbific effect is produced through the agency of the nervous system. The ordinary so-called essential symptoms, the calor, rubor, tumour, and dolor of the ancient writers; the fever, pain, sweating and muddy urine, are but the usual accompaniments, though in a less degree, of sthenic inflammation in any important organ, such as the pleura, and these subside most generally in my experience when the tension on the cardiac centre is relieved.

I feel that it is not incumbent on me to notice in detail the patent objections that apply to the miasmatic, malarial, or germ theories, such authorities as Basham, Garrod, and Fuller, discountenance them; and these views are only entertained by specialists unimportant in number, and are unsustained by clinical observation. It may be stated, however, that no one has so far given proof of the existence of any special germ, or microbe, *always* present in the blood of the rheumatic patient.[2] And although much may be advanced in favour of the neurotic theory through the intimate connection that subsists between the nervous system and the processes of nutrition and secretion; neither have the neuro-pathologists as yet been able to establish on a sure basis the truth of their contention, nor have they in conformity with their convictions formulated any special system of treatment for its cure. I prefer to enquire upon what grounds the more numerous advocates of the chemical or lactic acid hypothesis endeavour to sustain their teaching, and to what extent, if any, they are justified by the results of observation and experience. Doubtless if great names sufficed for its establishment, such authorities as Prout, Todd, Basham, Sibson, and others, would amply supply the desideratum.

In the first place we may assert that to designate an excess of acid in the blood as the pathogenic factor of acute rheumatism, and to prescribe an alkali as its antidote is but to revive the old chemical theory of disease, when every ailment was attributed to an acid or alkaline condition of the blood, and when the remedy chosen was that most likely to neutralise the supposed abnormal departure, as Senator writes:—"Authors have occasionally recommended *alkalies* from an early period on theoretical grounds—viz., in order to antagonise the abnormal production of acid supposed to go on during rheumarthritis."[3] Formerly the adherents of the *materies morbi*, or chemical theory, were wont to adduce as conclusive evidence the constancy of premonitary fever, the symmetrical distribution of its

[2] Topoff indeed (Meditz Pribav.) states that he has discovered, and isoluted the pathogenic microbe of acute rheumatism in the blood of a rhematic patient; and *post-mortem* in the synovial fluid from inflamed joints and in the heart, and that the injection of the cultures into the external jugular vein of two rabbits, gave rise to acute articular rheumatism, with pericarditis and endocarditis; but, further confirmatory experiments are necessary to establish the fact as a law in the etiology of the disease.

[3] *Op. cit.*, p. 61.

lesions, the phenomena of metastasis, and the wide-spread signs and symptoms of acute rheumatism, and thence to infer its constitutional or hæmic origin; but this favourite argument is now urged by the neuro-pathologists as well, and even Senator appeals to the symmetrical distribution of its lesions as a proof of the nervous origin of rheumatic arthritis. They also relied, as confirmatory evidence, on the favourable results often apparent after the administration of alkalies, such as the salts of potassium, the natural antidotes of acids, whether within or without the body. More recently the chemical pathologists seem to have considered that their idea has been indisputably established by the experiments of Richardson, and of Balthazar (now Sir Balthazar) Foster, through the results obtained by the former after the administration of lactic acid to cats and dogs, and by the latter to two men suffering from glycosuria; and upon these experiments and limited results "this very neat hypothesis, resting upon these somewhat slender bases," to adopt the words of Dr. Ord principally depends. Dr. Ord, however, further adds:—[1] "As resting on their observation, and that lactic acid has been found in the blood during acute rheumatism, is supported by names of great authority"—a statement to which I must take execption, whether adopted by Dr. Ord, or merely attributed to the owners of "names of great authority" referred to in his able address.

I trust that I shall be able ere I conclude to demonstrate in a satisfactory manner the insufficiency of the data, and the inconsequence of the conclusions arrived at, as well as the danger to which scientific truth is liable through a too implicit reliance upon authority, however eminent or respectable. Senator summarily disposes of Richardson's conclusions by saying "that it never met with much favour in Germany, and, indeed, it has lost whatever little credit it enjoyed since Moller and Reyher proved the results of the above-mentioned experiments to be erroneous. I have already stated that the experimental demonstration which Richardson tried to furnish by injecting lactic acid proved a failure."[2] Senator, however, seems to have been more favourably impressed by the speculations of Foster, "who has recently published some observations conducted on the human subject, which prove in a more striking way than any experiments on the lower animals possibly could do, that a disease completely analogous to polyarthritis may be produced in man by the administration of large doses of lactic acid. Foster's experiments were made on two diabetic patients, in whom the prolonged administration of lactic acid invariably produced the disease in a perfectly characteristic form, the symptoms always subsiding when the medium was continued. Kuêlz has quite recently observed the same phenomenon in a diabetic patient who was treated with lactic acid. The above consideration appears to me to indicate that the theory of the accumulation of the lactic acid in the system deserves more attention in the pathogeny of rheumarthritis than has been hitherto accorded to it."[3]

The next important pronouncement I shall refer to occurs in the otherwise excellent memorandum on acute rheumatism, the joint production of Dr. J. Goodhart and Dr. Thos. Barlow, issued in the name of the "Collective Investigation Committee," and published in the *British Medical Journal*, of April 22nd, 1882, and is as follows: "We are still ignorant as to its etiology; we have no accurate data in regard to the influence of food, and beyond the curious but well-established observations of B. Foster on the appearance of a quasi-rheumatic affection of joints, and under the administration of large doses of lactic acid, physiological chemistry has as yet given us no help." But, recently a more redoubtable combatant has entered the lists, to do battle for the chemical theory, in the person of Professor Latham, of Cambridge, who, in the Croonian Lectures for 1886, "On Some Points in the Pathology of Rheumatism, Gout, and Diabetes, has laboured in numerous pages of chemical formulæ of most elaborate and abstract character to demonstrate its truth with mathematical precision, and to reduce the argument to the simplicity of a chemical equation. The reader of Dr. Latham's erudite lectures is conducted through a labyrinth of intricate decompositions and recompositions, and transmutations, bewildering to ordinary comprehensions, but evidently satisfactory to the author, who appears convinced that he has succeeded in solving the riddle of causation.

By discarding lactic acid, and adopting uric acid as the primal cause of rheumatism, he has simplified the issue by so much; and while admitting the *rôle* of the central nervous system in its pathogeny, he assigns to it but a secondary position, as due to the action of uric acid in excess upon the vaso-motor centres, which, failing to control the vessels of the various affected tissues, thus indirectly gives rise to the gouty and rheumatic symptoms. The abnormal presence of uric acid in the blood is owing, he says, to the non-transformation of glycogene into urea. As one of his friendly critics remarks, "he appears to regard the body simply in the light of a complex laboratory. He is very fond of chemical formulæ, and has certainly made good use of them in explaining, or attempting to explain, some of the changes occurring in the organism; while some of his deductions appear to us far-fetched and highly hypothetical, we must acknowledge that many of them are very ingenious and suggestive, and as such we accord them every praise"[1]—just so. Agreeing with Charcot and Hutchinson, Dr. Latham appears to recognise the existence of an arthritic basic diathesis, a stock from which branch out two main divisions, or so-called evolutionary manifestations, and apparently proceeds to reason thus: gout is an arthritic disorder, attributable to the presence of uric acid in the blood; but, rheumatism is also an arthritic disorder, and is therefore caused by similar agency—an acid, lactic or uric; and having postulated in this manner, he proceeds to the proof, by the process of deduction, a procedure which, in the words of an accomplished writer already quoted, "first assumes the hypothesis, then assumes its absolute truth, and next reasons down to facts." His essay also proves that "if we may fairly assume that the deductive method is vanished as an acknowledged scientific instrument from the domain of pathology, it is equally certain indications of an unfortunate disposition to return to it every now and then make their appearance."[2]

Doubtless we often observe a hybrid coalescence of gout and rheumatism; and gout may supervene on rheumatism, and rheumatism be followed by gout, yet, although there exists a close relationship between them, they are nosolo-

gically distinct diseases. It may indeed be urged after perusing the very learned disquisition of Dr. Latham, that although he may not have succeeded in demonstrating the presence of an acid factor in the blood, it may nevertheless be present—true! but to this assumption one can only apply the maxim of the schools: "*de non apparentibus et non existentibus, eadem est ratio.*"

As to Foster's experiment, previously referred to, it is pretty evident that while, by the free administration of lactic acid to two diabetic patients, he undoubtedly evoked symptoms of arthritic disorder ("quasi-rheumatic," Goodhart and Barlow called them), it has yet to be proved that he had any justification in designating them as of rheumatic character.

To quote from my paper "On the Pathology and Treatment of Acute Rheumatism," published in the *Dublin Journal of Medical Science*, October, 1881: "The lactic acid hypothesis has been called into revived consideration by a paper in the *British Medical Journal*, of December, 1871, by Balthazar Foster, with the title of 'The Synthesis of Acute Rheumatism,' in which he published two cases bearing on the point, and expressed the opinion 'that these facts which have recently recalled me to my allegiance will strengthen the evidence that points to lactic acid as the poison of rheumatic fever.' The observations arose incidentally from an enquiry into the effects of certain drugs (among the rest, lactic acid) on the sugar excretion in diabetes. It is not my intention to question the correctness of the facts adduced by so accurate an observer. The results are quite consonant with the recognised effects of lactic acid. I must, however, take exception to the conclusions deduced from them, and beg to offer a solution more in accordance, I believe, with the true clinical significance of the published signs and symptoms. In the first place, Wright, ill with diabetes, and who had never suffered from rheumatism, is fed on a strictly animal, nitrogenous diet, a diet which, in healthy persons, predisposes to a certain blood disease—not rheumatic, however. Consequent upon the internal administration of the lactic acid, he had six attacks of articular pain fairly attributable to that agency; but, when we come from synthesis to analysis, we find that instead of mentioning 'acute pains in the joints, and flying pains about his limbs,' Foster particularises the joints affected. He says, 'the small joints of the fingers of both hands, the wrists, and, in a less degree, the elbows had become red, swollen, and painful; moderate perspiration, and heart clear.'

"*Second attack*, after six days dosing. On April 4th he complained of having had a bad night from joint pains, which came on *suddenly after midnight*. On examination, the metacarpo-phalangeal and first phalangeal articulations of the first and second fingers of each hand were found to be red, swollen, hot, and painful. The slightest movement aggravated the pain, and he could not, on this account, pick up anything with his fingers. The heart sounds were clear. The acid was then stopped. In the evening the pain in the knuckles was less; the redness had diminished. No other joints were affected. There were, subsequently, other reproductions of these symptoms in the knuckles, wrists, and elbows, and on two of these occasions the knees were stiff and painful, alternating with each other.

"In Case II. the patient, after taking the acid for four days, came to the doctor complaining of a sharp pain in his right knee, rendering walking painful. *No swelling or redness of the knee or other joints.* Again, after an interval, and the free administration of the acid, he found him in bed with pain in his elbows, shoulders, ankles, and knees, and all over him. None of the joints were swollen, except the right knee, which was faintly red, decidedly swollen, tender, and painful. The case is of little worth; the only joint swollen was the right knee, which was *faintly red.* How unlike an attack of acute rheumatism, in which we look for an initial rigor, for swelling, redness, and pain in the large articulations, excessive sweating, muddy urine, and cardiac affection." Does it not more clearly realize our conception of gout? which selects the smaller points for its habitat, makes its onset in the night? and what more efficient plan could we adopt to induce an attack of gout than by prescribing for a diabetic patient strictly nitrogenous food, accompanied by large doses of lactic acid, whose congener uric acid is always present in excess in the blood of the gouty? We cannot in this enquiry overlook the fact of the intimate connection that subsists between gout and glycosuria. Garrod states that gout and diabetes occasionally occur in the same individual; and Dr. Dyce Duckworth, in a very suggestive paper which appeared in the *British Medical Journal*, March 26th, 1881, refers to the remarkable relation that exists between these diseases. "Diabetes mellitus," he says, "is met with in certain members of gouty families, some having regular arthritic attacks, others incomplete gout, and others again, gout alternating with glycosuria. The gout alternates with uric acid. I believe that many cases of temporary glycosuria are due to gouty conditions, and that the alliances between these two states are very intimate. In both the gouty and the diabetic the law of heredity holds good, and the nervous system is involved; the same dietetic habits lead to each; the same classes of persons are affected; and the same exciting causes, such as tend to exhaust and depress the nervous system, will evoke both."

Dr. Ord, in the Address in Medicine already referred to, states that in more than one-third of his cases of diabetes true gout was distinctly present, that Drs. Gairdner and Lauder Brunton pointed out their frequent association, and asks whether in many people there may not exist a more or less constant arterial hyperæmia of the liver comparable to the acute hyperæmia of the joints, undoubtedly an essential factor of acute gout. Thus it would appear that B. Foster's cases are most probably instances of glycosuria and incomplete gout, present in the same individual; and one can understand in what manner lactic acid, either pure or altered in its passage to the blood, might react on the sugar or glucose in the system, and speedily change the saccharine to the acid fermentation, and thus arouse in the diabetic subject the latent symptoms of gouty disorder.

B. Foster has not told us whether, after changing the character of the blood by the action of lactic acid, there was any diminution of the glycosuric formation, or a complete suspension or alternation, such as Dyce Duckworth speaks of; nor that he had thought of applying the test supplied by Sir Alfred Garrod for the presence of uric acid in the serum of the blood. Had he done so, its presence or absence would have aided one way or other in determining the true significance of the factitious arthritic attacks. One of his latest critics, Dr. Fagge, writes of the result of Foster's experiment and his production of arthritis, "the symptoms of which seem to have resembled those of acute rheumatism." For so far, it has not been alleged that the administration of

lactic acid to a non-glycosuric subject has elicited any symptoms of arthritic disorder.

We have now to consider whether the results of the alkaline plan of treatment of acute rheumatism tend to prove the existence of a causal *nexus* between an acid condition of the blood and specific arthritic inflammation; and while in this enquiry we must freely admit that the administration of alkalies, notably of the potash salts, will neutralise free acid in the stomach, in accordance with chemical laws, and control the acid reaction in the urine, and may even succeed in inducing an alkaline condition of the system, with a corresponding improvement in the symptoms, it does not therefore follow that the popular theory of its *rationale* is correct, and that if critically examined it may not be capable of demonstration that it is not to its chemical, but to its vital action on the system the improvement should be accorded.

According to Guttman, Ringer, Bartholow, and other authorities, potassium and its combinations are essentially heart depressants and poisons, their physiological action being manifested through the medium of the cardiac ganglia. When a large dose is suddenly precipitated on the heart, its movements are speedily arrested; paralysis follows, and the arrest of the heart takes place in diastole.

Dr. Paul Guttman, quoted by Ringer, says that potash salts are all more poisonous than soda salts, and that they are depressors and paralysers of the heart. Bearing this fact in mind, Dr. Garrod modifies his alkaline treatment of acute rheumatism by combining with the potash salt a cardiac tonic and sustainer, as much as five grains of the alkaloid in the form of a carbonate, with thirty of the alkali from the very first, being given every four hours. The effect of the drug upon the patient must be carefully watched, and the amount and frequency of the dose varied accordingly, or if necessary, stopped.[1] That the salutary influence of potassium on acute rheumatism is not derived from its merely alkaline properties may be fairly inferred by contrasting with it the effects of the administration of the salts of sodium, or other typical alkalies, in this disease; sodium has but little toxic action, and but to a slight degree alters the composition of the blood. According to Bartholow, "in respect to the merely alkaline properties there is a close correspondence between potassium and sodium; but as regards other properties, there is a wide divergence. The salts of soda are alkaline, and hence, neutralise the acid of the gastric juice. The composition of the blood does not appear to be altered by them in any reasonable quantity; they do not promote oxidation in the system; and they cannot be used as substitutes for potash salts in the febrile state." Schönlein states that in large doses in frogs soda rarely arrests the heart's movement, only slowing and lengthening the contractions; and Paul Guttman, quoted by Ringer, "affirms that soda salts, in twice or thrice the quantity that proves fatal in the case of the potash salts, produce no effect on the system but a passing weakness. Even in large doses, soda salts excite no action on the heart, cause no diminution of the temperature, and produce no apparent effect on the cord, brain, nerves, or muscles." And ammonia, though powerfully alkaline in its reaction, and an effective antidote to acidity of the stomach, and *primæ viæ*, is seldom or never prescribed for the cure of acute rheumatism.

And thus, with three alkalies intimately allied in chemical affinity, equally potential in neutralising gastric acidity, yet widely differing in their other medical qualities, we find but one of the trio relied upon in this country for the relief of a painful disorder dependant, we are told, upon hyper-acidity of the blood and tissues; and while one is noted for its absolute neutrality and inertness in heart dynamics, and another is remarkable for its power of rousing the heart's action and stimulating the circulation, the third—the only alkali capable of lowering or depressing abnormal cardiac excitement and disorder—the potash salt is the sheet anchor of the chemico-pathologist. From this comparison it would appear that the calmative influence of the potash salts does not depend on their chemical properties, but on their vital action as cardiac sedatives or depressants; and further, that if the chemical conditions subsisting in acute rheumatism were regarded in their true light, and as epiphenomena merely, the *rôle* of alkalies in its treatment would obtain a greatly diminished significance. But, argument apart, the experience of eminent writers and authorities acquired by the most delicate chemical experiments and observations is adverse to the existence of lactic or any other acid in the blood or serum of the rheumatic patient in such amount as to constitute a satisfactory explanation of its cause. For myself, I have never been able, after many examinations of serum removed by a blister from the cardiac region, or that of the joints, to discover a trace of acid, the fluid being uniformly intensely alkaline in reaction, and coagulable by the application of a very moderate amount of heat.

Bristowe says: "It has even been maintained that the poison is either lactic or some other acid. No excess, however, of any such acid has yet been detected in the blood or perspiration of rheumatic patients; and if there be a rheumatic poison, which is possible, its discovery is in the future."[1]

Mitchell Bruce writes: "The blood has frequently been subjected to chemical analysis, but without any positive result of a pathological kind, the reaction of the liquor sanguinis is alkaline as in health. The amount of urea is not above the normal. Neither uric acid, lactic acid, nor any other abnormal principle, has been found in the blood during an attack of acute rheumatism."[2] Senator's opinion is that "the very existence of such excess of acid in the system is a mere hypothesis."[3] And Dr. Garrod declares that "after repeated analyses no abnormal principle has been found in the blood. Lactic acid has been assumed to exist, but no proof has been given of its presence." And again, "From acute gout, rheumatism may be separated by the absence of uric acid in the blood."[4] Additional testimony of a like nature might easily be afforded; but in the present state of the medical mind, so prone to revert to the humoral pathology in cases of difficulty, it might be practically unavailing. In the words of Dr. A. Davison, addressed to the Section of Medicine at Belfast in the 1884 meeting of British Medical Association, "It would be some time before existing theories or views as to the connection between acute rheumatism and the presence of certain morbid products in the blood could be subverted. It was impossible to explain the chemical phenomena of it solely by the changes in the blood, but it was quite impossible to deny the nervous system a very powerful influence, even in ordinary acute rheumatism itself."

(To be continued.)

THE PRACTICAL USE OF TRUSSES, AND THE OPERATIONS FOR RELIEF OF STRANGULATION.[1]

BY EDWARD BELLAMY, F.R.C.S.,
SURGEON TO CHARING-CROSS HOSPITAL.

TO ATTEMPT to condense such a subject as hernia into a single lecture is not only difficult, but absolutely impossible. I propose, therefore to discuss in some detail its more ordinary forms, symptoms, diagnosis (differential and otherwise), and treatment. I shall tax my own practice and experience in the views I bring before you, as it happens in that branch of surgery to have been fairly extensive. I may, of course, state that I mean by hernia, hernia in its accepted term, and to restrict myself, at any rate to-day, to the diagnosis and treatment of protrusions through some weak point in the parietes of the abdomen. The consideration of intra-abdominal herniæ, intestinal obstructions and occlusions, I must defer to some future date, if we have the time and opportunity. Indeed, their disassociation, from extra abdominal herniæ, is often a matter of extreme difficulty, and is possibly almost empirical, unless, of course, there is some evident hernial tumour, again, the conditions may be co-existent.

Definition.—I understand by hernia, in its ordinarily accepted sense, any protrusion of gut, part of gut, omentum, viscus, or part of viscus, through a *natural* opening in the walls of the abdomen, which may, or may not, have become dilated, owing to certain circumstances. Again, such a protrusion may take place through some adventitious aperture, but I do not consider such cases as within our series to-day. As a rule, any protrusion originally takes place *gradually* along some canal or opening, distending it *en passage*. We must be occasionally prepared for natural canals being afforded even by apertures for blood-vessels, or after ascites, or repeated pregnancies. Parts become so relaxed, and unable to resist normal pressures, that unexpected passages for gut protrusion are afforded, all of which contingencies the surgeon must be prepared for, and endeavour to differentiate between in his diagnosis.

Normal Anatomy in general.—I cannot here take up any amount of our time in anatomical detail, though please remember that operations for the relief of hernial constrictions are strictly anatomical, though not of necessity of the purely dissecting-room character.

Sac.—From a considerably long experience in teaching, I have noticed how vague the general idea is as to the nature of the "sac." Now, as to the sac itself (I shall speak of its "recognition" in my more practical remarks), its nature in relation to its contents, and to the abdominal walls.

Formation of Sac.—A knowledge of the method of the formation of the hernial sac is of great practical importance. The pouch-like prolongations of the parietal peritoneum are either congenital, or are the result of some local strain on the abdominal walls, or they may be caused by the dragging of some fatty mass in the sub-serous cellular tissue, which is drawn outwards, pushed against the skin, dragging the peritoneum with it. The latter is the general condition met with in crural hernia. On the other hand, the oblique external inguinal herniæ are generally congenital, as also are umbilical. Once the sac exists, it is of necessity dragged upon and enlarged by intestinal pressure. More gut gets into it, and it, of course, becomes bulkier. Of this nature are most frequently congenital inguinal herniæ, which go on increasing, and sometimes attain such an enormous size that almost the entire intestinal canal may be contained therein. Speaking generally, the form of the sac is pouch-like, with a more or less constricted neck. If the serous membrane at the terminal aperture, against which the peritoneum is pushed, takes on any considerable thickening and contraction, the *neck* is formed, which is of the greatest importance, as the most frequent seat of strangulation. Sometimes we find the neck of the sac relinquish its normal position at the hernial aperture, as, for instance, when the peritoneum is reflected upon itself, and also the sac pulled up; or if the hernia, perhaps owing to its weight, tears the neck of its sac by traction downwards and outwards. The sub-serous cellular tissue in the hernial sac is sometimes atrophied, sometimes hypertrophied, rarely, perhaps, locally attached to the adjacent parts. In crural and direct internal inguinal herniæ we meet with the so-called *fascia propria*, and we know of it well as a dissecting-room fact, and possibly in actual practice. It may be the locale of the fatty processes already alluded to. If this sub-serous fat accumulates to any extent, we get a "fatty hernia." I have met with such cases, and they are very difficult of diagnosis. It is advisable to mention here that such herniæ have not always a sac, and that these "fatty herniæ" develop lipomata, rendering both diagnosis and treatment complicated. The sac may be entirely absent, and when

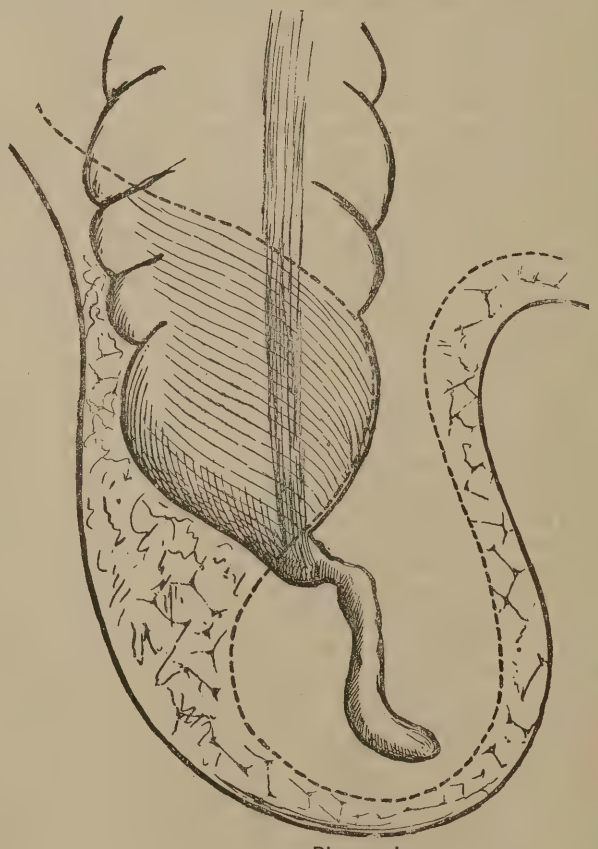

Diagram I.

not met with, is almost limited to hernia of the iliac aspect of that portion of the caput cæcum coli, where uninvested by peritoneum (*vide* diagram 1).

Its structural changes, I need hardly say, are of the greatest

[1] Abstract of Post-Graduate Lecture.

import in diagnosis and treatment. The sac is liable to alteration from its normal condition from long-continued irritation, want of nutrition, and, what is most common, I think, inflammation, resulting in adhesion, and frequently, and most important, in great thickening, near, or often happening in the *neck* of the sac, as in a case I operated on recently, where the sac was certainly as thick, and looked very much like, coloured wash leather.

Coverings of Hernial Protrusion.—Practically speaking, the most important of the coverings of a hernia is the *fascia propria;* possibly the most constant met with during operation, as it so rarely gives way. It immediately invests the sac, and may be mistaken for it by the unwary, and, like the sac, being subject to pressure, it becomes thickened and adherent, and simulates it most closely in its relations at the neck of the sac, and it is only after its division that we can define its actual condition, and by so doing we may reduce the hernia without opening the sac, an important factor in our decision as to its opening or non-opening. Moreover, it *looks* very like the sac, especially in femoral hernia; but I have often called the attention of students to the fact that owing to its *continuity* to the *margins* of the rupture—the ring, in fact—it appears to be prolonged upwards, whereas if the sac is exposed we can feel the defined margins of the constricting portions, which we can rarely do unless this fascia be divided.

Contents of Sac.—Now as to the *usual* contents of the sac—speaking merely of gut, for most untoward events occur—(1) if intestine alone, *enterocele;* (2) if of omentum only, *epiplocele;* (3) if both, *entero-epiplocele*, occasionally extraordinary contents are met with; but as a rule we find, small intestine, ileum, lower part of jejunum; and if large intestine, caput cæcum, or a bit of the sigmoid flexure.

Classification of Herniæ.—First of all, *Reducible*. The term itself might be taken to be obvious, though in actual practice this is often not the case. As a rule patients suffer so little; they are aware of their condition; they can either, themselves or their doctor, "tuck" up the protrusion, and feel as well as ever directly afterwards. They often overlook, or possibly underestimate what may turn out to be a very serious contingency. This condition may have, and generally does appear gradually, or there may have been some sudden effort to account for it, at any rate, upon the hand being placed over the swelling, a distinct impulse is given on coughing, and most likely an increase in its bulk. The recumbent position is often enough to cause reduction, at any rate the surgeon's finger, if gently introduced into the canal, will accomplish it, and this reduction, in the event of gut, is almost always associated with the peculiar "gurgle" so satisfactory to our ears. If omental, the reduction is not so easy; there is a more tough, doughy feel, and no gurgle. In entero-epiplocele the gut is usually the first returned, followed by the omentum.

As a *rule*, then, the process of *Reduction* is this: The patient recumbent, shoulders and pelvis slightly raised, lower limbs partially flexed on pelvis and adducted, for the purpose of relaxing the abdominal muscles, the mouth kept open so as to prevent undue action of the diaphragm, or straining. The swelling should now be pressed with one hand gently in the direction of the canal, whilst the other directs the pressure at the neck of the sac, thus guiding it into the abdominal cavity.

Trusses.—Here, I think, a few remarks on the use and proper application of trusses may be of value. I do not intend to weary you with anatomical detail or nomenclature now; I will demonstrate these points in my demonstration on the dead body. I will make a few remarks as to the measurements and particulars required in ordering a truss. I quote from Professor Wood: "State whether the hernia or weakness is a right or left one, or both. Give some idea as to the size of the protrusion. State whether the opening through which the hernia escapes is large or small, and give a description of the hernia. The truss should be constantly worn, except when the body is in the horizontal position." Here I cannot quite agree with my teacher, Professor Wood; it should always be worn. "The spring should be sufficiently opened to go round the right leg; it should be placed round the left leg, and afterwards drawn into place, and the pads adjusted in their proper position after the rupture has been perfectly reduced. It is very important to remember that a duplicate truss should be used in all cases, not only for the sake of cleanliness, but even for the sake of change. The great principle to remember is that a rupture must always be kept up."[1]

Irreducible Herniæ.—I now come to the most important portion of our lecture—viz., those conditions of hernia which would threaten life were it not for prompt measures—and here in their treatment, the functions of the anatomist, pathologist, and operator are blended, or should be.

Before commencing, we must have distinct ideas as to nomenclature, and which, I consider, must be founded on anatomical facts. There are conditions which are not necessarily attended with immediate danger, and they may be described thus: (1) A hernia may be irreducible from adhesions between it (or omentum) and the sac, thus preventing reduction; and it does not follow that the protruded portion of bowel is interfered with, so far as its peristaltic action is concerned; but the element of danger in these cases is that the protrusion may become inflamed, and strangulation ensue. (2) If a hernia has been left unreduced for some time, it may happen that from alteration in form, or, according to Spence, some increased deposit of fat in protruded omentum, may so far add to bulk that it cannot be returned into the abdominal cavity. In such a case, if taken in time, and before adhesions have taken place, by proper manipulation, well-regulated pressure and cold, as well as the recumbent position, the hernia may be reduced. (3) In a third class of cases it may so happen that the hernia is irreducible on account of its great bulk, and has formed a sort of secondary cavity for itself external to the abdomen—a state of things occurring most commonly in large umbilical, scrotal, ventral, or possibly femoral ruptures. In this cavity the hernia lies, and may threaten strangulation, and, as in a case which happened to myself, which I brought before the Clinical Society, an operation for its relief *merely relieved* the contents of the preternatural pouch.

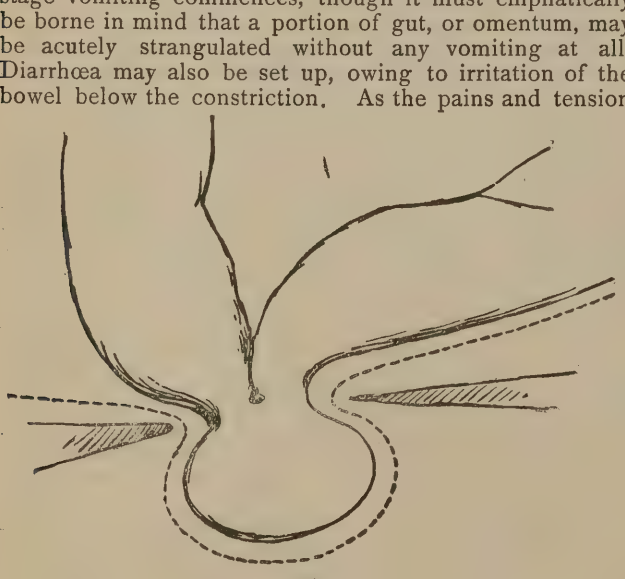
If the hernia becomes irreducible through acute constriction, incarceration, or strangulation, danger is imminent, owing, of course, to interrupted function of the knuckle of gut, omentum, or both. It may be followed by peritonitis and sphacelation.

Perhaps the term *Incarceration* requires a more careful interpretation than generally given. I look upon it thus: It is one of degree, and is the early stage of *constriction* before complete *strangulation;* in fact it is the preliminary stage of strangulation. The term *Constriction*, again, should

[1] Wood: "The Application of Trusses," p. 32. Matthews Bros., London.

be correctly understood. It takes place in the following way, remembering that the constricting elements of the protrusion are the fascial tissues, or the neck of the sac, and that the muscular tissues, though favouring the condition, do not *imprimis* cause it, we find that in the majority of cases where strangulation occurs the hernia has existed for a long time, and the openings through which it passes are *dilated*, and not contracted, and the fascial or peritoneal margins, pressed upon by the protrusion become thicker, more condensed, and the denser structures become more resistant and oppose dilatation. Hence it is that, if fresh gut or omentum descend, or such gut becomes distended by fœces or flatus, an altered relation is set up between the gut and the tissues constricting and indenting it. Then congestion from interrupted venous circulation commences, swelling, distention, and strangulation.

Strangulation.—Let us thoroughly understand what this means. We have nearly arrived at it, in speaking of incarceration. It may be stated thus: *irritation and swelling of the protruded gut*, leading to such general symptoms as follow. To take a typical case of a hernia, if let alone, passing from a state of acute incarceration to strangulation and gangrene. In the first place the patient may have had, and possibly has had, a rupture for years, able to reduce it, but, on occasions, he has been unable to do so after, we will say, some exertion. The patient usually complains of sickness and griping, and tenderness over the site of the rupture. Owing to the peristaltic movements of the intestine being altered, venous engorgement occurs, and gases become evolved in the gut, the constricted portion becomes more tense and distended, and the indentation caused by the constricting fascial or sac margins more deep. The pain increases, and, possibly, at this stage vomiting commences, though it must emphatically be borne in mind that a portion of gut, or omentum, may be acutely strangulated without any vomiting at all. Diarrhœa may also be set up, owing to irritation of the bowel below the constriction. As the pains and tension



Littre's Hernia.

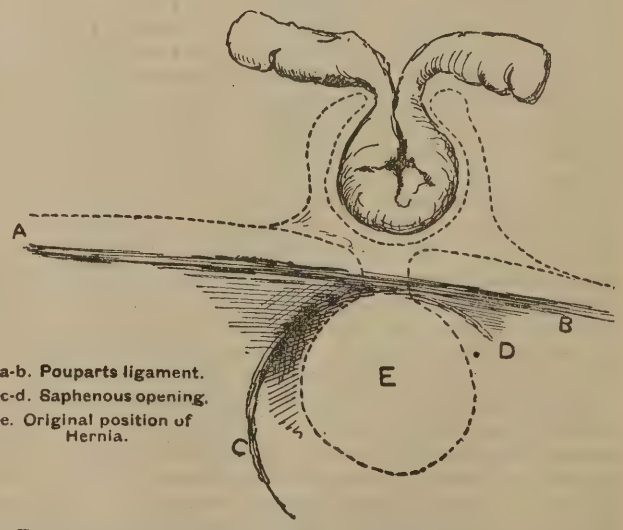
increase, so does the abdomen itself become more tense and tympanitic, and the vomiting more frequent. The pulse quick, skin hot and feverish, tongue moist and furred, and generally headache. On further progress, it may so happen that the protrusion, or tumour, is less painful, but the integument becomes of a dusky red; the pulse small, wiry, irregular, and the vomit now distinctly fœcal.

Examination of Hernial Tumour.—The skin becomes cold and clammy, the *facies Hippocratica* (or *herniatica*, as I call it—it is so well marked) comes on, the hiccup or attempts at vomiting more frequent, these symptoms pointing to commencing gangrene of the gut, and unless we relieve the patient by operation, there is a fatal result. The same symptoms may result in cases of strangulated omentum, or in such a case where only a portion of the lumen of the gut is nipped, as in *Littre's* hernia, or a constriction of a Meckel's diverticulum.

Taxis.—And now, a few words on what is understood by taxis—an attempt, often a successful one, to return a hernia into the abdominal cavity and into its proper position without recourse to operation by any cutting process. I may state, *ab initio*, that if the two procedures, operation or taxis, were compared as to danger, I most certainly regard taxis as the more dangerous, for reasons I will presently explain. However, to apply taxis, without an actual case before us, it is very difficult to explain what is so depending on judgment and "touch."

Failure of Taxis.—Immediately operate; all further and persistent attempts at reduction will do more harm than an operation. The extra-peritoneal operation will in most cases suffice, supposing the hernia to have been down twenty-four to thirty-six hours, and symptoms are not *very* urgent; but by continuing taxis we are not at all sure what we are doing, and on operation being performed it will be found what *harm* has resulted from manipulation. I think that fatal results occur from *delay* in operation, and that the condition of the gut prior to it is the cause. *Urgent* symptoms should *never* be waited for. To begin with, it is illogical. In the event of diagnosis, even with symptoms not being quite clear, no harm can be done by operating, especially with our modern methods of combating its supposed dangers. Hence the axiom, "*When in doubt, operate.*" You will never regret it, and may for ever regret *not* operating.

CASE I.—Plan of Reduction en masse.

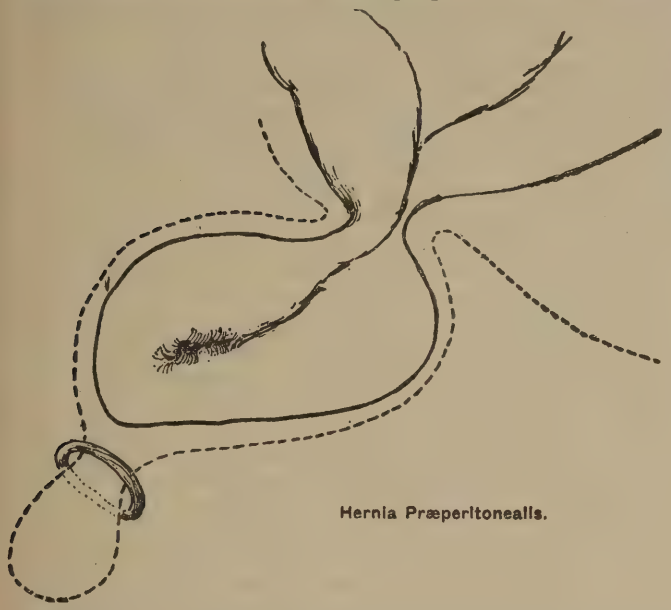


a-b. Pouparts ligament.
c-d. Saphenous opening.
e. Original position of Hernia.

Dotted lines indicate peritoneum.

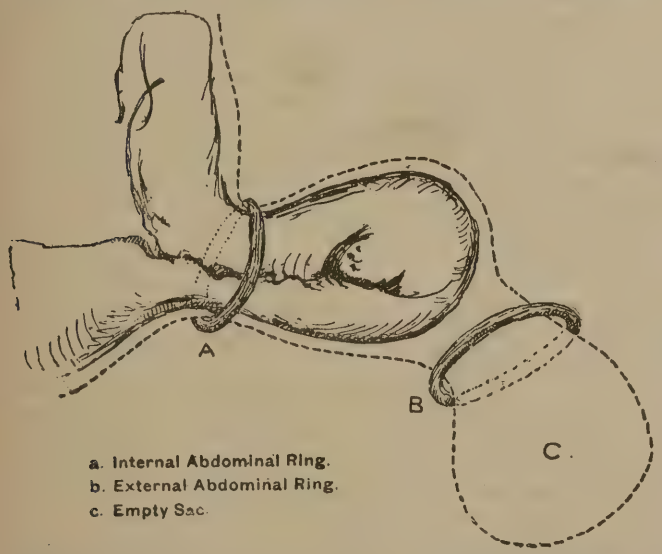
Reduction en masse or en bloc.—With regard to this condition, the chief points are the more usual forms of such reduction and treatment; definition of reduction *en masse* in the condition, when the sac and bowel are reduced behind the rings. I show you some sketches of the several forms of this reduction. The one occurs in inguinal herniæ,

when the knuckle of gut is reduced merely through the external ring, remaining in the canal, and still bound by the inner ring. Again, the neck of the sac, if it lies very high up, and which has been pushed up behind the inguinal canal, can easily lead up to this mistake. Such instances are termed *hernia præperitonealis*. Another



Hernia Præperitonealis.

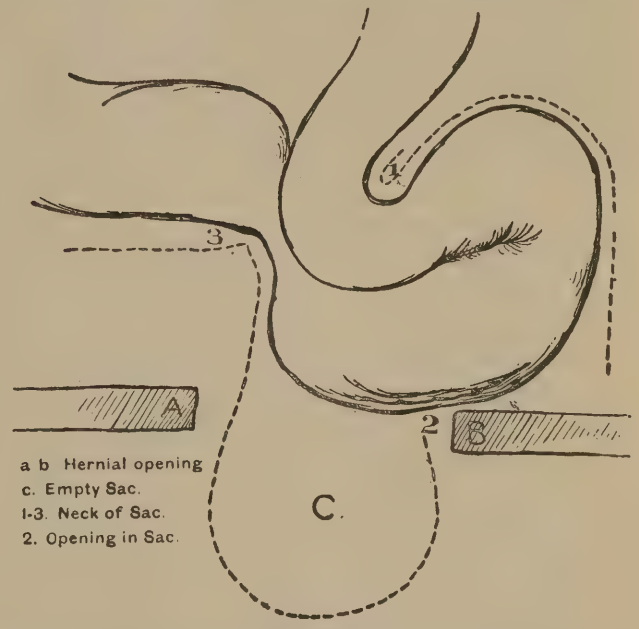
mishap occurs in herniotomy, and it is this (it has occurred to myself)—one performs, as one imagines, the operation *secundum artem*, the surgeon divides the sac near its neck, or if you like at, its neck, and pushes up the coil of gut; and



supposing all well, and that the gut is absolutely replaced, he finds afterwards (*i.e.*, supposing the case a fatal one) that the gut is strangled at its sac's neck, twisted on one side from the sac itself, and tucked up between the peritoneum and parietes (*fascia transversalis*, etc.)

Again, we may meet with cases where the constriction may take place in some abnormal pouch or foramen, the folds of peritoneum, or in some false membrane, or from complication, twisting, distortion, or kinking, still continuing after the supposed reposition of the parts.

Extra-Peritoneal Operation.—The principle of operation is the same in all cases. We should aim at exposing the part where constriction exists, and then can be seen exactly the parts requiring division. It is clear we cannot see the condition of the gut but by this method, so therefore, in reducing we must be very careful not to do so *en masse*—a state of things apt to occur if the sac is not opened, as I think, the extra-peritoneal operation is only proper in very recent operations, and not justifiable after forty-eight hours. In the slightest doubt of fitness for return, I always open the sac. I say, always examine the state of the gut at its constriction, gently draw down the bowel *from above*, and an opinion can be then formed, for if there be any show of gangrene, its return may be fatal.



Recognition of Sac.—Supposing an uncomplicated case, this is often difficult. The sac is covered by some loose cellular tissue, devoid of fat, bluish, and as before said, generally containing a coffee-coloured fluid. If, however, it has been irritated, it may present as thick, pale, dense, or fibrous.

Description of Operation.—All the proper antiseptic, or cleanly precautions having been carried out in absolute detail, an anæsthetic should be administered, if available, and the patient completely narcotised. The line of incision depends, of course, on the anatomical position or relations of the tumour to the ring and its surroundings, varying naturally in the different forms of rupture met with. The integument should be boldly, but carefully opened in the long axis of the hernial tumour, and at the same time, the locality of the constriction sought for. After carefully dividing the fascia, as a rule the contained fluid between the sac and the bowel, if not actually seen, is felt. The sac should now be pinched up, the knife lateralised, and cut through tangentially to the axis of the gut. A skilled operator will cut as freely through the sac as through the integument. I personally never use a director, and I believe it to be capable of doing great harm in clumsy hands. The pulp of the fore-finger, which is the best and safest director, must now be gently introduced into the sac.

We can now see the condition of the knuckle of the gut, or of the omentum, or of its contents. If gut, and if it

is seen to be of a deep red-blue or brownish colour, undoubtedly return it. If it is found to be black, or even with a black spot—I was going to say on its surface merely—an important re-consideration—*operate at once.*

The absolute position of the constriction ascertained, a probe-pointed bistoury or hernia knife slid flatwise along the finger's pulp, cautiously pushed between the pulp and the sharp ridge of constriction, is then turned at right angles to it, when an unmistakable *feeling*, perhaps *hearing* of "giving way," convinces the surgeon that he is so far right. The next procedure is reduction, which may or may not be difficult; but my experience is that if the constriction be properly divided, and the bowel healthy, it is simple enough. When we are quite sure the hitherto constricted portion of gut is really returned within the abdomen, we proceed to deal with the sac. This consists in most instances of ligature of the neck of the sac, and its subsequent removal. Sometimes, as happened to me the other day, the sac, after reposition of the gut, is found to be as thick as wash-leather, and not unlike it in texture and appearance, complicating the operation.

(*To be continued.*)

A LECTURE ON SOME OF THE CLINICAL RELATIONS OF ALBUMINURIA.[1]

By ALFRED G. BARRS, M.D. EDIN., M.R.C.P. LOND.,

ASSISTANT PHYSICIAN TO THE GENERAL INFIRMARY AT LEEDS; LECTURER ON PHYSIOLOGY IN THE YORKSHIRE COLLEGE OF THE VICTORIA UNIVERSITY.

I PROPOSE to take up in this lecture a few of the more important, and perhaps interesting, conditions under which albuminuria is apt to arise, or with which it may be associated. In the first place, perhaps one would not be wrong in saying, for all practical purposes, that every case of Bright's disease is a case of albuminuria, but not every case of albuminuria is a case of Bright's disease. This statement, trite as it may seem, will serve to emphasize what is too often forgotten in practice—the all-important duty which devolves upon us of saying whether, in a given case, the presence of albumen in the urine means grave disease of the kidneys, or is only an indication of some general condition of no serious import, or, it may be, the result of some misbehaviour of parts structurally healthy.

From this little it will at once occur to you that a useful division of cases of albuminuria into those which are due to one of the forms of Bright's disease, and those which are not, is one which at any rate is readily made on paper, though perhaps not so readily made in actual practice. To decide that the presence of albumen in the urine is due to structural disease of the kidneys is, by implication in most cases of chronic disease (and it is in these that difficulties most often confront us), to condemn the patient, sooner or later, to death. Still I think for practical purposes the case may be stated in this bare and definite way, though one does now and again hear of cases in which the diagnosis of chronic Bright's disease has been made upon apparently unequivocal evidence, but life has not, in consequence, been unduly short. Professor Gairdner said, in the discussion on albuminuria at the Glasgow Pathological and Clinical Society in 1884, "There is no doubt that the immense importance attached to the pathology (*i.e.*, the pathological anatomy) of the kidney since the time of Bright has tended to create an impression that what we call Bright's disease is more hopeless and more incurable than it actually is. It has been over and over again observed, in the history of medical research, that the first flush of pathological enthusiasm has for one of its results to concentrate attention on the dead body, and thereby to throw into the background the early stages and curable forms of disease. The gloomy prognosis, the gloomy aspect, which has been given by the relatively too assiduous attention to pathological anatomy, and by our not being always able to follow out for a sufficiently long time our clinical experience tending in the direction of cure, still clings to the pathology of this very important subject. Nevertheless, I think every practitioner who has had a large enough and long enough experience, and who has been able to keep many of his cures long enough in view, must have satisfied himself that very ugly-looking cases of Bright's disease, and even cases of the forms that are most regarded as incurable, sometimes come to something like suspension, or at all events to a modified cure for the time during which they are under observation."

Still our difficulty here is, as in most other diseases, the interpretation of physical and other signs observed during life. All Professor Gairdner's warning means—and it means a great deal which ought constantly to be borne in mind—is this: that the same external manifestations do not always mean the same internal structural defects. There can be no doubt of this did certain conditions of the urine, and certain conditions of the heart and vascular system, with dropsy and certain symptoms of a less objective character, *always* mean, say, the large white kidney as we know it in the *post-mortem* room, such certain conditions of the urine, and other signs, would always mean death, and nothing less; but it is not so, and this is the important fact to grasp, though the fact is, I fear, only very occasionally to be observed.

Dr. Grainger Stewart[1] has recently, in a paper to which I shall again have occasion to refer, divided cases of albuminuria into those which are dangerous to life and those which are not so. This classification, which differs very little from those I have already indicated, simple and obvious as it is, is all that is really required from the patient's point of view, and by consequence from the point of view of the practitioner, for I need scarcely say the presence of albumen in the urine is, *per se*, of no importance whatever; it gives rise to no inconvenience to the patient, and even when most profuse constitutes no serious drain upon the system; but it is a condition easily and readily demonstrated, and consequently has come to be regarded as the outward and objective sign of some derangement in the urinary organs, specially the kidneys, and as such to always require the most careful investigation.

It is from this point I would venture to look for a few moments at Bright's disease, as manifested by conditions which result from impaired normal functions of the kidneys, the conditions to which the term, uræmia in its wider and generic sense may very properly be applied. The *raison d'ètre* of the kidney is, no doubt, the elemination of the products of nitrogenous destruction, mainly in the form of urea. The water, though an excellent vehicle for such solid matters, is by no means an important factor. Were it necessary to get rid of water by other channels than the kidneys, such channels are ready to hand in the skin and lungs. We now know, whatever the *modus* may be, that when the amount of nitrogenous material separated by the kidneys falls below a certain point in quantity, that certain symptoms very soon arise. The most common and most

[1] Delivered in the Post-Graduate Course at the Leeds General Infirmary.

[1] *American Journal of the Medical Sciences*, January, 1887, p. 34.

important condition in which this happens, is that in which the kidneys are the seat of those changes which constitute in one of its many phases Bright's disease. This condition is, I would say, constantly accompanied by the presence of albumen in the urine, in very varying quantity, but albuminuria there is always. The exception usually made to this rule, in the case of granular kidney, I believe to be based upon very doubtful observations.

We have, then, at least two methods at our disposal for investigating the functions of the kidneys; a third method, that of the direct examination of the organ by means of touch, is practically useless, and altogether unavailable for our purpose. The two methods I refer to are the observation of certain manifestations, due to the retention of urea and its congeners in the system; and the second, the direct examination by chemical procedure of the urinary secretion in this respect. This latter is usually the outcome, and so to speak, the graphic representation of the former. It is to the former that I wish now to direct your attention.

This serious chemical defect in the blood must of necessity make itself felt continuously and uniformly, so long as it exists upon all the tissues and organs of the body. The manifestations then of the conditions will be as various as the ever varying conditions of the organs in health themselves. The nervous system, the respiratory system, the circulatory system, and so on, all suffer in their own peculiar ways. The general and obvious uræmic condition is one too gross to need description, but it is on the other hand important to recognise the fact that there may be one single manifestation attaching to one single organ or system, which surely indicates the presence of a grave, and it may be a mortal condition, far advanced, in one who to the superficial observer may be in perfect health.

First of all I shall speak of the shortness of breath occurring in those suffering from chronic renal disease. Persons the subject of chronic albuminuria are liable to many conditions causing shortness of breath, such as pleural effusion, inflammatory or otherwise, pulmonary œdema, cardiac failure, and the like; it is to none of these I refer, but to a form of shortness of breath having several varieties which is not explained by any physical conditions, including those I have mentioned. This dyspnœa is just as purely a functional disturbance of the nervous mechanisms involved in the respiratory process as the uræmic convulsions is of the nervous mechanisms involved in the movement of the limbs. This nervous character of the shortness of breath in question has long been recognised, and is clearly admitted, in the name which it has long borne of uræmic or renal asthma. The fact that people, obviously the subjects of renal disease, suffer from a functual shortness of breath has long been known, but the point I wish to make is this: that not unfrequently patients present themselves for the shortness of breath alone, who have not, and never have had, any of the ordinary systems of chronic Bright's disease. So far as my experience goes this uræmic dyspnœa without uræmic symptoms is just as frequently overlooked as the same shortness of breath occurring in diabetics who are free from lung or cardiac complications. The dyspnœa of uræmia proper may be simple and continuous, with occasional exacerbations of a spasmodic type, and perhaps this is its commonest form, and a form of which the uræmic origin is most commonly overlooked. A typical case of this I saw only a few days ago. A stout, rather pallid woman, with marked stigmata on the cheeks, æt. fifty-three, presented herself, complaining of shortness of breath, sinking and low spirits. This dyspnœa was quite obvious, even after she had been lying on the couch for some minutes during an examination of the chest and the abdomen, and varied from twenty-eight to thirty-six or forty respirations in the minute. The examination of the chest revealed nothing abnormal. Even the heart made no suggestion of albuminuria, and I very much believe that the dependence of all her trouble upon the renal condition would not have been determined except for the routine examination of the urine of all patients, which rule I endeavour to follow as consistently as circumstances will allow. The urine was pale, copious, perhaps 100 or more ounces in the twenty-four hours; had been noticed to froth much; of sp. gr., 1008, and loaded with albumen. Other indications of the woman's real condition there was none. No uræmia either of legs or face; no hardness or slowness of the pulse, except one thing, she had vomited, and vomited frequently in the early morning before taking, as well as after her meals. Still till after the examination of the urine, even this did not impress me any more than it had impressed a most reliable practitioner, under whom she had been treated for some months as a case of dyspepsia, and other ailments incident to a toothless woman of beyond middle life. The moral of this and similiar cases would be, if I dare venture to point to it, examine the urine of all patients at every and any opportunity, and especially in all cases of shortness of breath not clearly explained by lung or heart condition. Examine it both for albumen and sugar, for though I have seen many cases of dyspnœa dependent upon an undiscovered albuminuria, I have seen as many dependent upon an unobserved diabetes. We are so constantly misled by the statements of patients. A simple inquiry as to whether the urine is natural or healthy, whatever the term may be, being usually answered in the affirmative if it is the copious urine of Bright's disease or diabetes, and in the negative if it is the rather concentrated urine, loaded with lithates which most of those who are in good health are in habit of producing. I believe a good plan in making inquiries in this matter is one which I have adopted in the out-patients' room, that is, to always ask directly for nocturnal micturition and its frequency, and in the case of men always when possible to see the patient micturate.

To revert to the uræmic dyspnœa, another interesting example of the condition occurred in the case of a man, æt. forty-six. Ten months before admission he had been much exposed to wet and cold from which he suffered much, but in no definite manner, and was able to go on with his employment. There had been no œdema of the leg or face, or change in the urine noticed at the time. He had attended in the out-patient room here for dyspnœa, without physical signs, until one day the legs being found to be œdematous, it was thought necessary to admit him into the house. His breathing than even when lying undisturbed in bed, was thirty-six in the minute, and the respiratory movements were prolonged and laboured. On auscultation, corresponding alterations of the breath sounds were heard, but no adventitious abnormal sounds were observed. He was passing an average of fifty ounces of urine daily; sp. gr., 1018; loaded with albumen. The subcutaneous injection of pilocarpin in half-grain doses relieved him more than the use of nitro-glycerine, which was at that time coming into fashion in the treatment of uræmia.

Another case under my observation at about the same

time showed dyspnœa of a distinctly Cheyne-Stokes, or ascending-descending type. This form of breathing is seen in many cases of uræmic coma, and in coma from any cause; also in some forms of cardiac disease, but is not commonly, so far as I know, known to denote the uræmic state in its milder degrees. In this case the average breathing was forty-four per minute; urine, sp. gr., 1020, and loaded with albumen. *Post-mortem:* the kidneys weighed eighteen ounces, and had appearances rather of granular and interstitial veins than of large white forms. The heart weighed thirty ounces. Of the paroxysmal forms, closely resembling spasmodic asthma, I have seen no example, and of the form coming on in exertion and so simulating aortic disease, I have seen no case, but Dr. Howard,[1] of Montreal, has recorded a case of uræmic dyspnœa coming on only on exertion, and also to make the likeness to aortic disease more complete, accompanied by anginiform seizures. Œdema of the glottis as a cause of dyspnœa in acute Bright's disease is well known, but its occurence in chronic cases, though recorded, seems to be of great rarity. I need scarcely say that we are dealing only with a symptom, though one of a very distressing nature, and one which naturally strikes the sufferer more readily than slight œdema of the ankles or some change in the urine as the case may be, and it is for the reason that this may be the only aspect of the case which is presented to us, that I have ventured to bring it before you in this manner. The condition admits of no treatment other than that of the uræmic state upon which it depends. The asthmatic cases would probably be benefited by the use of the various preparations of the nitrites, or any of the well-known anti-asthmatics. Otherwise pilocarpin, digitalis, hot-air baths, and other diaphoretics, will meet the cases so far as they can be met.

HEALTH RESORTS OF THE WORLD.

XXIV.—THE RIVIERA AS A WINTER HEALTH RESORT FOR TROPICAL INVALIDS.

By J. E. FISHBOURNE, M.D., F.R.C.S.I.,

FORMERLY ON THE MEDICAL STAFF IN INDIA, EGYPT, ETC.

IT seems almost to require an apology for making an attempt to dilate upon the Riviera as a winter health resort, the subject having already been, apparently, so thoroughly threshed out by various writers, yet as my enquiries have so far led me to believe that the location has not hitherto been considered as a winter and spring health resort, more especially for those whose health may have suffered either from prolonged residence in warm climates, or from actual disease incurred therein, it has occurred to me that some remarks on the suitability of the locality for such persons, or invalids, might not be thought amiss, especially as having had nearly a quarter of a century's experience of tropical and semi-tropical countries and their diseases. Therefore the subject may possibly prove of interest to those members of the profession, who not having had an opportunity of visiting foreign countries and studying their complaints, may nevertheless be called upon to advise patients suffering from diseases of hot climates as to the most suitable winter and spring health resorts for their maladies. To such a perusal of these notes may perhaps help somewhat towards doing the best for the sufferer; and if of use to only a few, the labour may not be quite thrown away. Having had, as said above, a pretty extensive practical acquaintance with such diseases and their treatment, I do not therefore approach the subject without some show of reason. Again, having observed on many occasions the ill-effects of a sudden change of climate from the burning plains of India, to the too often cold, foggy, damp climate of old England, on invalids suffering from tropical disease, it may be allowed to be an additional reason for venturing to put these remarks before the profession, as perhaps the personal experience of one who having himself suffered from long residence in India, etc., and who has also experienced the benefit of a winter and spring residence on the Riviera for old Indians and their disorders, may be of some account. Nor is the subject by any means a new one to many, as for a number of years past it has been a matter of frequent notice by those medical men brought much in contact with tropical invalids how seriously the sudden change, from the warm dry climate of India to the cold, damp, foggy climate of England, often affects their case, and how difficult it is under such circumstances to hope for improvement till the patient becomes "re-adapted," as it were, to the change. So much had experience forced this baneful influence on those medical men who have had most to do with invalids from warm climates, that they have frequently thought it advisable to recommend them to try, as soon as possible after arrival in England, a more suitable climate for their cases; and my object is now to endeavour to draw attention to the fact that within thirty-six hours of London we have a most suitable winter and spring health resort for such cases, as far as my experience enables me to judge.

Now, the advisability of getting many tropical invalids out of the chilly, damp climate of Great Britain during winter and spring is an old story, and one that had received notice many years ago by the medical men at Netley, in India, and elsewhere. So much so, that the English Government went to large expense in establishing a hospital and sanatorium at "Suez," where suitable cases, invalided from India and the east during winter and spring months, might be disembarked *en route* to England, and left till the weather at home had become milder, and less likely to injure their health, or they had become sufficiently recovered to proceed. But anyone who knows Suez will perhaps agree that it is not by any means an interesting or lively spot after a week's stay, and that although the manifest advantages of its winter climate for tropical invalids was allowed, yet its dullness and isolation made it a most unwished-for place to be left behind at, and that invalids preferred all the risk of going straight home. In vain did their medical attendants expiate on its advantages for their complaint, and the chances of their health soon becoming sufficiently restored so as to enable them to follow on as soon as the weather further north had become milder. No doubt it would be difficult to make Suez either lively or interesting, but the fact was forgotten, or perhaps had to be left out of consideration, that invalids and sick people require some amusement and distraction as well as ordinary mortals, and that something besides physic and regimen is often requisite to aid towards recovery. So the place became gradually disused, and was hardly likely to become a fashionable health resort, as invalids before long wished themselves out of it, so that being left there became dreaded, and an order

[1] *Canada Medical and Surgical Journal*, November, 1884, p. 193.

to proceed home highly desired. However, be that as it may, as whether the sanatorium was considered hardly worth the expense, or whether other reasons led to its gradual effacement, deponent knoweth not, but it became deserted, except during the Soudan expeditions for sick and wounded soldiers, when its value was recognised again. It was no wonder invalids did not take to the place, for who that has spent long years of exile in the far east cannot but know what a magic effect the thought of going "home" has on the sick and weary exile, or the wonderful tonic and bracing effect the idea of being soon amongst one's own kith and kin once more exerts on the poor debilitated sufferer. But, alas! the medical attendant has often to notice with regret how soon this tonic effect wears off, and that only too rapidly the novelty of being at home again fades away, the patient remaining either at a standstill, making no further progress towards recovery, or even getting worse, the cold, damp, chilling climate of an English winter, or spring, acting prejudicially on the tropical invalid. Here it is where I believe the medical attendant is wise if he recommends the sufferer to seek a more genial climate, and why I am anxious to call attention to a climate and locality admirably suited, in my humble opinion, for such cases.

Now it hardly requires a medical training, or experience, to grasp the fact that the cold damp of our English winter and spring must have a prejudicial effect on many tropical invalids, and do much to retard their recovery; and why? Because the resident of a temperate climate, who has spent long years in a hot, dry climate, like that of India, must have his internal economy —as it were—more or less put out of gear and disarranged by the sudden change home, the skin, amongst other functions, being accustomed to act very freely in the hot country, the kidneys being thus relieved of much of their functions, and the liver called upon in India to do a lot of extra work for other organs. Now the change of climate must necessarily considerably disarrange all these organs, the cold, chilly weather, etc., having the effect of driving the blood from external parts to the internal organs, and those organs already perhaps damaged by disease. The alimentary tract and digestive system, as well as the nervous organisation, have also probably suffered, or are the worse for long tropical wear and tear, so that although the medical man treats the case most carefully and well, he finds his patient does not improve in health. But my experience leads me to believe that a change to a winter climate like that of the Riviera, where three days out of four are bright and sunny, gives the patient, as well as the doctor, a much better chance, and remedies applied before in vain get opportunity of acting beneficially. And this is not theory alone, as I am able to vouch for the wonderful improvement soon visible by the change. For not only is the thorough change of air most desirable and grateful, but the complete change of scene, as well as the dry bracing air, fine sunny days, enabling the invalid to take out-door exercise, all tend to put new life and hope into the sufferer. Now most medical authorities are agreed that the climate is a moderately dry, stimulating one, admirably adapted for convalescents after most debilitating diseases, but on this point I hope to say a few words further on.

I will now proceed to make some few remarks on the climate and physical geography of the Riviera for the information of those who have not the large guide books and medical works on the subject at hand, or perhaps leisure to wade through them. A glance at a map will explain the reason why the "Riviera di Ponente, and Levante" enjoy such a mild winter climate, equivalent to that of countries many degrees further south. For on the north we have the Maritime Alps and other ranges of mountains, protecting us from the north and north-west winds, and to some considerable extent from north-east also, which blow over our heads, and curl the waves of the Mediterranean into "white horses" many miles out. We are therefore placed, as it were, on the south side of a high wall, basking in the sun, whilst well sheltered from the cold winds of Northern Europe. The wall of limestone which protects us absorbs a quantity of heat during the day, helping to make the night air warm and genial. We have, of course, no thorough immunity from all the winds that blow, as naturally the heated air ascending causes currents from colder regions to arrive to fill the gap, as it were. Of these the "*mistral*," or north-west wind is the most important, but from this we are well protected at Monte Carlo, the hills on our north-west keeping it from disturbing us much. A north-east wind sometimes blows as well, but seldom, and from this also we have ranges of hills to break its force. We also have occasionally a south, or south-east, wind, the "*sirocco*" from the African coast, which is laden with moisture after crossing the Mediterranean, causing rain, but is a rare visitor. The temperature during the winter and spring months seldom falls below 50° Fah., except at night. For instance, Monsieur de Brea, a French authority, gives the mean annual temperature of Mentone, a few miles to our east, during ten years observation, as 60.8° Fah.; whilst Dr. Henry Bennet, after twenty-five years observation, puts the winter and spring temperature as 51.7° Fah., and the mean difference between wet and dry bulb thermometers during winter and spring months as 5.1° Fah. only. Sir James Clark gives the mean annual temperature of Nice, ten miles on our west side, as 59.48° Fah., or say 60° Fah. in round figures, with a winter and spring temperature of 52.05° Fah., which closely agrees with those of the observers at Mentone. The mercury seldom touches freezing point, and then only at night during very severe winters; in fact it is most unusual for it to reach 40° Fah., so that frost is almost unknown, and "*like angels visits, few and far between.*" Snow is also a rare visitor even in hard winters further north, and then only a few flakes, which melt as they reach the ground. Fogs, too, are practically unknown, the only approach being mists on neighbouring hills at times. Winds, as I have said, are kept off to a great extent by our ranges of protecting hills, and seldom cause annoyance, or keep people indoors. In consequence, dust is rarely seen, a great comfort for invalids. Again, the invalid can safely count on three days out of four being fine enough for out-door exercise from 10 to 4 p.m., as Nice shows a rainfall of twenty-five inches yearly, or thirty-six rainy days only during winter and spring months, Mentone exceeding that amount somewhat, they say. The climate can therefore be said to be a dry one, with a mild stimulating effect on most invalids. Monsieur de Brea, the French meteorologist, gives Mentone as enjoying 214 fine days with sunshine, without clouds; forty-five with some clouds, but sunshine as well; twenty-four fine days without rain, but cloudy, no sunshine; and only eighty days in the year during which rain falls, but of these many are not pouring wet days, as the sun shows itself during a considerable number. Let those at home, perhaps accustomed to four or five wet winter days a week, ponder over these facts.

When it does rain it sets its mind to it well, getting over the salutary and needful process quickly.

Another climatic peculiarity, interesting to invalids, is that the mean annual difference between the maximum temperature during the day, and the minimum during the night, exhibits a range of only 12° Fah., showing a very equable temperature, and disposing of the fallacy that the climate of the Riviera is a moist one. There is one matter which it may be well to draw the attention of invalids to, and that is the necessity of being indoors always before the sun disappears behind the western hills, as sundown is a "dangerous" period of the day, becoming suddenly cold and chilly, and apt to cause colds and chills to invalids, or even healthy individuals, unless warmly clad. It is therefore judicious for all to be home in time to escape the chilly period, which soon passes away, and is succeeded by soft warm evenings generally. The cause of the above conditions of temperature is no doubt due to the ascent of air heated by the sun's rays, and the rushing down of cool air from the mountains to replace it. Nature herself, a sure guide, affords ample proof of the mildness of our winter climate at Monte Carlo, for on looking around what do we behold. The delicate and heat-loving lemon tree flourishing in profusion, the orange, the olive, numerous palms, as well as the eucalyptus, growing in the open air, and flourishing all through the winter. The invalid may also feast his eyes on roses in full bloom on Christmas Day, and heliotrope, as well as violets all through the winter. Again, we may behold geraniums and pelargoniums begin to flower in March, as well as different species of mesembryanthemum. Varieties of chrysanthemums and cacti flourish in the open, the former in flower in December. Petunias, carnations, and violets, also many kinds of salvias, nasturtium, and marguerites bloom in the open all the winter. Cypresses, pines, bananas, and bamboos in profusion, as well as aloes, whilst growing wild we can pick numerous wild flowers and shrubs, such as wild thyme, rosemary, pansies, violets, myrtle, etc. Habrothamnus elegans, ageratum, osteospermum, and datura stramonium flower all through winter; also petunias flowering in February. Carnations, wall flowers, and pinks flower early in spring; narcissi and tulips also begin to flower in January and February; also crocuses and snowdrops, as well as ranunculi and salvias. Ficus roxburghi, imperialis, and schaufieri; also aralia dactilifolia and humboldi; also bonquaimilea glabia and spectabilis grow at Monte Carlo in the open, but no where else on the Riviera, I understand.

But I think enough has been said to show the mildness of our winter climate at Monte Carlo, which most people, who are not interested, allow to be as fine, if not better, than any other place along the Riviera, it being, as said before, so shut in and well sheltered from cold winds, etc. A visit to the beautiful gardens of the "Cercle des Etrangers" ought to convince any person, knowing something of horticulture, that the winter climate "*must*" be a mild one to permit the flowers and plants he sees there to flourish in the open air all through the winter season. The advantages of such a winter and spring climate for tropical invalids need hardly be enlarged upon, enabling them to spend so much time in the open air, if strong enough, particularly of use for those convalescent after any debilitating illness, and acting in a mild stimulating manner on the whole system; in fact, a "climatic tonic."

One great feature in its adaptability for invalids is its comparative "*proximity to England, and its easy access.*" For instance, London can be left one morning, and the Riviera principal health resorts reached in time for dinner next evening, travelling in quick through trains, with sleeping carriages attached, without changing, if desired, once the train is boarded at Calais. The "train de luxe" is also a luxurious, but expensive, mode of coming out, as it travels rapidly and comfortably, without the necessity of changing—a great advantage for sick or weakly people. If desired, invalids on the way home could disembark at Malta, whence Marseilles or Genoa can be easily reached by steamer, or the Orient line will land them at Naples, whence the locality can be easily reached; or, if preferred, a sea voyage by the P. & O. Steamer to Marseilles from Gravesend, and then on by train to destination; in fact, there are many other routes, but this will suffice to show its accessibility. The accommodation for invalids is also good, as the hotels are fitted up in a most comfortable way, and the food and cooking excellent. Many hotel proprietors will take visitors *en pension* from ten to twelve francs per diem, or if rooms with a good south aspect are desired, a little more is asked. Villas are expensive, from 4,000 to 5,000 fr. and upwards, furnished with linen, plate, etc., for six winter months, but these would only suit should family accompany the invalid, and his means be good. Again, furnished rooms can generally be had at a much lower figure, the convalescent having his meals, if well enough, at some restaurant. Some of these restaurants are reasonable, giving a really fair dinner, wine included, for three francs, and breakfast for two francs. Furnished flats can also be hired at most places, and if two invalids "chum" together, comes to a fairly moderate figure. The food and cooking is generally excellent, and a thorough change, tempting the appetite, which, however, is usually soon restored, provided the invalid can take sufficient outdoor exercise, the air acting as a wonderful tonic. Warm sea baths can be indulged in almost all through the winter, the sea water being seldom below 50° Fah., so that up to December it is possible to bathe in the open air, provided the patient is robust enough. Should carriage exercise be desired, capital little victorias, with a pair of ponies that travel well, can be hired for three francs the hour. The clothing, of course, should be suitable. Serge, woollen, tweed, or flannel, with a couple of top coats, one good thick one for driving, and a lighter one for walking. Neutral tint eye preservers are also most useful, and a wide-awake (or terai) hat very convenient.

The French language will carry one anywhere, and the expenses need not exceed one pound per diem at outside. But if desired it can be done much cheaper, provided the invalid can get about and take care of himself. The season lasts from the middle of October to the middle of May, which is quite soon enough to travel home again. But should circumstances not permit, the invalid might arrive about the middle of November, and stay till the middle of April. Now what are the reasons for recommending the Riviera as a suitable winter and spring health resort for tropical invalids? Given a climate like, what I have endeavoured to touch upon, even the fringe, and given the fact that most medical authorities consider it so admirably suited for various lung diseases, for gout and rheumatic complaints, for disease of the kidneys, and in fact as a "tonic" for convalescents from most debilitating diseases, my idea is it must also be suited for invalids from hot climates; and why?—because it enables them to be out of doors three days out of four; because it improves their appetite, gives refreshing sleep (except in a few

abnormal instances), allows the skin to act, and do its share of blood purification, gives the lungs a chance of breathing a bracing atmosphere, not too moist, nor yet too free from moisture; improves digestion and liver action; in fact braces the whole system up, whilst delighting the senses. Given such a climate, which is, as said before, so generally allowed by experienced physicians as an excellent one for most lung complaints, especially of any inflammatory origin; which is of great benefit to rheumatic gouty constitutions; which allows the skin to act and relieve diseased kidneys of extra work; which does not drive the blood by cold into internal organs, therefore relieving the liver, kidneys, spleen, and intestinal tract from danger of congestion; which allows the patient to inhale an abundance of fresh air, and take exercise most days in the week; which wards off to a great extent dangers of bronchitis, and is so often of marked benefit to the asthmatic and emphysematous lung sufferers; which is frequently of signal service to neuralgia, relieves the dyspeptic, is found to be markedly suitable for the aged, most salubrious for children, who instead of being cooped up indoors in England most days of the week, can run about in the open air almost any day, and bathe in the sea ten months out of the twelve. May I not therefore say that a locality suited for all such cases must also be admirably suited for invalids suffering from the effects of tropical disease, or debility, or broken down by repeated attacks of malarial fever and ague, or with enlarged liver, or weak intestinal action after dysentery, diarrhœa, or enteric fever; or those recovering from the effects of sunstroke; in fact, any invalid almost, requiring a nice winter bracing climate, cannot, in my opinion, do better than give the Riviera a trial. Far better than remaining cooped up in London lodgings, with cold and fog as an almost everyday companion, with a wish to be able to breathe the fresh air of heaven, which cannot be indulged in, however, without graver risk in our variable English winter climate. Should the medical attendant have such a tropical invalid who does not improve in spite of all his care and judicious treatment, let him advise him to try a stay in the sunny south, a change from the fog, cold, and darkness of a London winter's day; almost "like a fairy scene," as I have heard those who have tried it exclaim. I am sorry it has not been possible in a short notice like this to enter more fully into the medical aspects of the question, but feel sure that medical men will be able, by their own experience, to fill up any gaps for themselves. My object will be gained should they only be led to ponder the matter over in their mind in case they come across patients from warm climates, who they consider might benefit by the change of air, scene, food, etc., such as I have attempted to describe.

XXV.—THE LINCOLNSHIRE FENS.

Almost exactly midway between Boston and Lincoln, on the left hand bank of the Witham, the attention is arrested by a noble, red brick tower rising to an elevation of a hundred feet above the plain. With the exception of Layer Marney Tower in Essex, a grander structure of the kind is not to be found in England. That splendid specimen of fifteenth-century brickwork is Tatsall, or, perhaps more correctly, Tattershall Tower; it owes its existence to Lord Treasurer Sir Ralph Cromwell, and was built between 1430 and 1440. It was a time of transition between the Middle Age and the modern era: life and property were becoming more secure, though occasional tumults and out-breaks were still to be feared: the mansions of the nobility, although no longer requiring to be massive castles, primarily intended for defence, continued to need sufficient strength to resist an assault: hence their thick walls and embrasure-like windows. The country round Tattershall is attractive in a certain curious fashion. Hills there are none, woods are scarce, trees are small, and miles may be traversed without passing anything beyond an occasional bush, but it would be incorrect to describe the scenery as tame and uninteresting. The rich soil, the luxuriant grass, the splendid crops, and the slow moving rivers, speak of plenty and enterprise. Moreover, the contrast between mid-Lincolnshire and the undulating country south-west of Salisbury is very marked, and the visitor is all the more struck by it if, as has happened to me often, he is fortunate enough, in the course of a summer day, to pass from Woodhall or Kirkstead to Axminster or Honiton. The contrast is undoubtedly pleasing, while there is something indescribably exhilarating in the interminable plains of the Fen Country—a sense of illimitable vastness, of boundless freedom unfelt in those lovely but narrow southern valleys, which in another way are so soothing and so peculiarly English. Some of my readers, whose lot has fallen in typical woodland scenery, in the midst of green shady lanes and lofty timber, may see little in the Fen Country. But what pleasure fills the visitor from the noisy and smoky towns of the West Riding and of Lancashire, when he gets to a part of the land where smoke is rarely seen, and the towns have much of the tranquility of nature clinging to them.

How Kingsley loved the Fen Country, and how well Tennyson has entered into the spirit of its scenery, its breezy freshness of atmosphere, and its beauty! Nowhere in England are the churches loftier and nobler! and nowhere else is the number of stupendous ecclesiastical edifices larger. Almost every little town boasts of the remains of an Abbey or Priory of the first rank, while some of the spires are lovely triumphs of art. I do not envy the man who could stand under the mighty Lantern of Ely and not perceive that the vastness of the great eastern plains must have inspired its designers and builders to commence and complete their Titanic labours! In the distant past, when the waters extended for leagues and the Hill of Ely rose a veritable isle in the midst of the floods, the mighty Cathedral must have resembled an ark resting on the sea. The country has the same character for many a league,—on past the magnificent temple of Peterborough, that, had money permitted, would have been crowned with a loftier spire than than of Salisbury, one which would have been seen fifty miles round,—on past the colossal tower of Boston, on, still to the north, to where the splendid pile of Lincoln dominates the town, and is a beacon to the surrounding country. What must Lincoln Minster have been before the ruthless hands of destroyers hurled down its heaven-pointing spires! We shall never rival those old monkish architects: they built for God and for eternity: one generation after another was content to raise a few additional feet of massive walls, leaving to the next the continuation of a task, which none who commenced it could hope to see completed. We build carelessly and hastily, and our work, devoid of beauty, conceived and carried out with little sense of religion, answers its purpose well enough and is swept away in a generation or two to be succeeded by other buildings as uninteresting and as little likely to resist the storms of many winters.

The Broad Tower of Lincoln is one of the grandest works that ever came from mortal hands. It rises 244 feet four inches to the gutter, and 271 feet two inches to the top of the vane: it once served as the base for a tall spire of timber, covered with lead, that rose 250 feet higher. The total altitude was 525 feet, or 121 feet loftier than that of Salisbury. This prodigious masterpiece of art was destroyed by a hurricane on January 31st, 1548. The great western towers continued to terminate in tapering spires till 1727, when the Dean and Chapter commenced taking them down. An excited and furious crowd collected, and the authorities were compelled to give way, and this time at any rate a popular tumult did good, and was justifiable. But in 1807 the impious hands of the treacherous custodians of the sacred edifice had full play, and the Dean and Chapter were not disturbed in a second and more successful attempt to remove the western spires. A few years ago some survivors of that remote age, could still tell strange tales of the loveliness of those matchless spires.

At Boston the handsome font, given by Mr. Beresford Hope, is a pleasing memorial of that good and generous man, who loved his country well, and her ancient Church still more. His zeal did much to give loftiness of aim and fixity of purpose to church-restorers who found his ample purse always ready to assist.

Somerset perhaps excepted, there is no part of England so remarkable for its innumerable abbeys, castles and ancient churches as Lincolnshire and the adjoining region: Selby, Louth, Grantham, Newark, Southwell, Fountains, Kirkstall, Beverley and Croyland are a few of the names that crowd into the mind. But Somerset, though remarkable for its grand towers, built under the fostering influence of Glastonbury, is not rich in spires and in vast churches, nor interesting for its castles.

Not far from Tattershall the train stops at a little junction —Kirkstead, where a grand Cistercian abbey, an offshoot of Fountains, was founded in 1131; only some insignificant remains mark the spot where it stood. A single line of rail connects Kirkstead with the sleepy old town of Horncastle, and a mile and a half from the former there is a plain and unpretending station—Woodhall Spa. A curious sight meets the eye—a town is being built, springing up with American-like rapidty from the plain. The spectacle is so unusual that one looks round with wonder for an explanation. No lofty chimneys meet the eye: no vast ranges of factories, no docks, no coal mines account for the sudden uprising of a town. The promoters of the place have had signal advantages; they had an unoccupied site flat as a table, and owning in their corporate or private capacity, all the country near, they with great judgment cut broad and straight roads parallel to the line, and built houses which for beauty, quaintness, and perfect sanitary conditions, leave nothing to desire. Moreover, they drained the plain in the most approved modern fashion, so that no water lies more than a few hours, and the day following heavy rain the roads are usually perfectly dry; the moderate rainfall of the district helping materially in making and keeping the place dry.

The rise of Woodhall has been curious and interesting. Many years ago borings for coal were begun, and vast sums were, as it appeared, thrown away on unsuccessful attempts, indeed, tradition says that £20,000 were lost. A shaft was driven to a depth of a thousand feet, and the workmen were much inconvenienced by the inrush of water; the latter was finally cut off by a wall, and the shaft had to be diverted from the perpendicular. After a time it was discovered that this water had properties making it of incalculable value in the treatment of disease; and in addition to the more ordinary constituents of mineral springs—common salt, carbonate and sulphate and nitrate of soda—it was found to be very rich in free iodine, besides containing large quantities of iodates, iodides, and bromides, and traces of peroxide of iron. A medical man settled in the place, a hotel was built, and visitors in small numbers made their way thither. Little by little the water became more extensively appreciated, and a couple of years ago five gentlemen, among them Mr. Edward Stanhope, Sir Richard Webster, and Mr. Henry Chaplin, purchased the place and commenced developing it. The singular composition of the spring and its reputation in the treatment of gout, rheumatism and some other complaints, forced the medical profession to confess that benefit would result in many diseases from a course of treatment. Then commenced the rapid development of Woodhall. Last year and the year before houses sprang up everywhere—large, handsome, red brick structures with red tile roofs, the upper story slightly over-hanging the lower, thus giving a quaint, Swiss-cottage appearance to the place; new baths were constructed and an able medical superintendent appointed, a gentleman whose long residence in Germany, large knowledge of the world, and excellent business capacity, fitted him for his difficult post. In the meantime, as the value of the land rose by leaps and bounds from £50 an acre to £430 or more, the syndicate were wisely lavish in laying out capital, and providing sumptuous accommodation for the visitors who came in numbers that, at times, exceeded the limited capacity of the place. All through the past year the work of extension has continued. The hotel has had its accommodation doubled, £7,000 have been laid out on the baths, a handsome pump-room has been erected, with a gallery for music in wet weather, and a large band-stand has been built in the open air for fine days. The Victoria Hotel is now perfect and leaves nothing to desire; while, as for the baths, the services of Major Davis, of Bath, have been called into requisition, and he has spared neither time nor expense to fit up a place a credit to himself and an ornament to the town. Every kind of bath has been provided—steam, needle, douche and sitz, while trained attendants give the patients requiring it the benefit of massage. The pump-room is fitted with every convenience for taking the waters, which are as useful internally as externally, and for which an enormous general demand has sprung up. The last medical novelty—the pine bath, can also be given at Woodhall to perfection, while the fittings of the bathing places are costly and are made of aluminium.

This is not all: greater attention is being given to amusements and sports than at most rising English health resorts, and the tennis lawns, the terraces beautifully adorned with handsome screens to cut off the wind, and the arrangements for music during the season, show that far sighted policy has ruled the plans of the managers. The enormous outlay incurred cannot, however, for years be remunerative, though no doubt the proprietors will not be losers in the long run.

I have spoken of the flatness of Lincolnshire and the absence of trees, but Woodhall is remarkably favoured; an extensive larch plantation adorns the place, and gives the hotel and the baths almost perfect shelter, while the size of the trees, the sweet aroma they diffuse, and the beauty of their scarlet flowers, are additional attractions.

The plantation, the baths and the hotel stand very near the station on one side of the line; still closer to the latter. but on the same side a couple of handsome blocks of picturesque shops have been built, and so great was the rush to Woodhall that it was curious to see that many half-built shops were occupied and apparently doing a large business, although the workmen were still hard at work upon them. The railway authorities have also acted prudently, and have purchased long strips of land for widening the line and building a large and handsome station, and late trains will, during the summer, run on Saturday nights to Horncastle, Lincoln and Boston. The town stands on the other side of the railway, but close to it; and in these times of depression it is refreshing to see such enterprise and activity, and to read on many notice-boards that the site is sold.

The syndicate and the railway authorities formally opened the Spa, hotel, and baths on Tuesday, May 22nd, 1887, with an official gathering, when an inspection of the place was made by a large number of invited guests. That was my second visit to the place. Three weeks earlier I had had the privilege of being escorted by the medical superintendent, Mr. C. J. Williams, and had been shown every object of interest. I felt, as I questioned him, first on one matter, then on another, that my visit was unlike any which I had paid to any other place—I was seeing a town in course of erection, a new birth among the health resorts of the land, and I experienced a sense of novelty that I shall not often know. As I stood on the platform in the early morning and looked at the sun, which had not long risen, I was again compelled to confess that Lincolnshire was not tame and uninteresting, but that one might get very fond of it and admire it as highly as the Welsh Borders and the Derbyshire Dales, with their noble timber, vast straggling hedgerows, and richly wooded heights.

Although I have described the Baths at some length I do not see why Woodhall should depend on them for its fame. With good fortune and skilful management it might in time become a great health resort like Cheltenham and Leamington, with many schools and a large resident population. It has disadvantages of position, which, however, handicap it, for unlike them it does not lie between great manufacturing centres, on a main line of rail. The branch connecting Lincoln and Boston, by which Woodhall is alone approached, is only a little frequented, cross country route and, still worse, Woodhall itself stands on a small branch leading only to obscure, dead alive Horncastle. Should Woodhall ever become an important place with a large demand for railway accommodation it may pay the Great Northern directors to give it a frequent service of trains, for both they and the Woodhall Spa managers must remember that it is the lower middle classes who build large towns and fill them, not the nobility. If the teeming hives of Yorkshire get to like the new health resort and flock to it, they will keep it full, and freely spend their money there, and a great future may lie before it.

SOME RECENT SCIENTIFIC ADVANCES.

By Alfred J. H. Crespi, Wimborne.

Scientific progress is continuous and distinguished by ever accelerating rapidity. Experts would have no difficulty in pointing out, year by year, the steps that had been taken and the direction in which further advance was certain and near. Not every year, however, would they have to record such triumphs as the introduction of saccharine, vanillin, and cocaine, but none the less could they point to discoveries, increasing the enjoyment of human life, diminishing the cost of living, and giving promise of still more rapid advance. Scientific discoveries are never made haphazard, though there is nothing on which the general public are less correctly informed. Were twenty most useful chemical compounds handed to a person not competent to judge of their value he would pass them by much as a labourer would fail to be struck by the finest passages of Dante and Shakespeare, and for the same reason—absolute inability to judge of their beauties and merits. Scientific discoveries are in these days, when the surface has been thoroughly explored, only within the reach of the highly trained investigator, who energetically and laboriously examines everything put before him, and no one but he knows how great are the manipulative dexterity and patient, untiring perseverance required to overcome difficulties. Hundreds of able enquirers are at this moment working in every department of science, toiling, thinking and experimenting, but in most cases with no advance to record, finding that the discovery they would make eludes their grasp much as the painter has often to turn to the wall, night after night, the canvas on which he has been vainly trying to portray features of ethereal beauty, but which he lacks the genius of a Raphael or a Lionardo da Vinci to call from out of his inner consciousness. When a discovery is proclaimed to the world of such a character as to captivate the imagination of mankind, and not one in twenty possesses the easy comprehensibility, and obvious utility enabling it to do that, it represents genius, patient research and vast attainments which only a few trained investigators can properly appreciate. People exclaim "What a wonderful discovery: what a lucky fellow," little understanding that he, whose name then comes before them for the first time, has shewn indomitable perseverance for years and deserves the same, yes and perhaps even greater fame than rewards the successful toiler in more popular walks. There is something so true and touching in the words of Dunsford in "Friends in Council" to his young girl friend—"always honour a scholar, my dear; if for nothing else, for the untiring energy, the sleepless toil which it has cost him to acquire that scholarship." And so, when we hear of some scientific advance we should never forget that it represents the labour of years, and that the one successful candidate for public recognition is perhaps the only man who has come to the front in a hundred who have striven to add to the sum of human knowledge, and who have seen summer fade into winter, and youth give place to age in the fruitless attempt. I have been fortunate enough to see much of some of these ardent students of nature, and I have known them live but to learn and discover; perhaps for weeks sitting up all night in the untiring struggle to master the mysteries of nature, hoping still in vain, yearning to inscribe their names on the long list of discoverers, and yet not unhappy in the midst of failure, for in the discharge of their self-appointed mission they have found happiness.

Sir Benjamin Brodie believed that observation, practice and thought were the chiefest means of self-training in science, but he did not underrate the value of labour—patient, well directed and continuous. On the day of his election as President of the Royal Society he remarked that he felt "his happiness to be in life of exertion." In my own case with no aptitude for scientific pursuits, lacking the patient application and accurate observation indispensable to the successful student of nature, I sometimes envy the men who have the power so to apply themselves, and half wish that I had been differently constitued so that I too

might have rejoiced in chemical researches or, like my clerical neighbour Augustine Chudleigh, have found more pleasure in dissecting a horse's foot or a rat, than in studying the masterpieces of literature.

Acquiring knowledge may at last become a passion giving a pleasure as keen as a constant round of gay amusements to persons of different temperament and less lofty ambition. Yet it must not be forgotten that this is a practical world, one in which men and women have to live and die, so that it is well that something fruitful should accompany the acquisition of learning. Professor Edward Freeman pours a torrent of biting invective upon the man, who looks for a substantial return for his labours, and who asks what good will result from learning. Mr. Freeman contends that anyone, worthy to be called a scholar, will toil merely to acquire knowledge and with no thought of future reward, and yet it is obvious that were not some thought given to the uses of patient and long-continued study, thousands of men might degenerate—I can find no other name for it—into mere bookworms, reading night and day it is true, but not increasing the sum of human knowledge, not enriching and enlightening mankind, but nevertheless having to be maintained by the labour of others. Surely the passion for knowledge as such may be carried too far and amount to little more than a clever man's hobby. Have we not all heard of the scholar whose wife, at the point of death, sent him an urgent message to hurry to her side, "Tell her," he replied, when he had with some difficulty grasped, so great was his preoccupation the meaning of the message "to wait a few minutes." Again came the imploring summons. Again the scholar pleaded for delay. And now he was informed that she was dead. He paused a moment, sighed, and resumed those studies, which had become dearer to him than life. There is something inexpressibly touching however, in the dying request of Lavoisier, that his death by the guillotine might be delayed for a short time so that he might complete some interesting experiments, and something not altogether unnatural on the part of the authorities—"that the republic did not want chemists."

Perhaps the field which at present is giving the greatest promise is chemistry applied to the arts of life. One can see no limit to what may there be accomplished. Not only is there a promise of far more durable materials, stronger drugs, and cheaper chemicals, but, above and beyond all else, a prospect of such advances that food will be built up in the chemist's laboratory, and inexhaustible supplies be poured into the market. Man has a tendency to multiply more rapidly than the means of subsistence: land can only produce a certain limited amount of food, and that is so dependent on the seasons, the latitude, and the depredations of insect and vegetable pests, that the actual yield from a given acreage falls, under the most favourable conditions, far short of the theoretical return. It is conceivable that the pressure of population might tax wide areas and demand more food than they could be made to yield. We have now nearly reached that limit in England: two thirds of our wheat and perhaps, on the average, close upon one half of all the food annually consumed in this realm is drawn from foreign lands. But supposing that chemical science should teach us to build up compounds, with dietetic properties equal to those of wheat and with nothing offensive to the palate, what a marvellous future might await the race, become independent of extraneous supplies. Many people will no doubt smile and assure us that the manufacture of such food, should it ever be possible, will not be economical and, therefore, not practically useful. But is there not continuous progress in theory and in practice: machinery is being rapidly perfected, human labour is being economised, and the stored up energy of the tides and rivers must before long be utilised. Later I shall have more to say about this. Let us by the way reflect on the energy that runs to waste in a single gale of wind, or in a single high tide off the coasts and in the rivers of our country. The stored up energy of all the coal in all the coal fields of all the world represents, in billions of foot tons, a mere fraction of the energy of the rivers of Europe, nay of England, and while the richest coal mines are soon worked out, and coal demands much labour for its transference from the bowels of the earth to the great centres of industry, there is just as much energy in the tides and rivers to-day as there was a thousand years ago. The wind too must represent an energy almost beyond the imagination to grasp. In a single heavy three days' gale the energy that could be extracted from a million of well placed windmills transmuted into electro-motor power, and properly stored would be worth untold millions and tens of millions of tons of coal. For motive power we shall not long continue to look to our coal mines: we shall utilise our rivers and estuaries, and perhaps learn to regard a stiff gale as an inexhaustible source of material wealth.

I can distinctly remember, when a little boy, seeing a brilliant electric light over the offices of the Elkington Electro Plate Works, in Newhall Street, Birmingham, on the occasion of the Prince of Wales's marriage. It was a marvellous achievement, and aroused general curiosity and attention—the wondering crowds looking at the dazzling light were a proof of this, but long after that time well informed people contended that the electric current could never be transmitted any great distance for practical purposes, and would always be ruinously expensive, while there was no possibility of its being divided. It was only yesterday, as it were, that we saw the exhibitions at South Kensington magnificently lighted up by electricity: The problem is solved, the current can be transmitted vast distances, houses and streets can be easily and economically supplied with it: nay more, its expense is rapidly diminishing, and holders of gas shares cannot doubt that before long, in spite of better methods of preparing gas, in main thoroughfares, churches, public buildings, railway stations and ships, the electric light will not only be the great illuminator, but that its economy over gas will be as pronounced as its superior lighting power. Of late marvellous progress has been made in that branch of mechanical art, which has as its aim the doing of work by means of the electrical current. Electricity, as every school boy ought to know, is no new discovery. Thales and his learned coadjutors wondered as they noticed that a piece of amber or *elektron*, when vigorously rubbed for a few minutes, attracted light bodies, and two thousand years and more later Dr. Gilbert, Queen Elizabeth's great physician, had got little farther in practical results than the Greek sages. Conjecture of course found an inexhaustible field in electricity, and Robert Boyle hazarded the suggestion that an invisible glutinous substance came out of resins and glass, when friction was applied to them, which seized hold of any light bodies within its reach, and then carried them back with itself to the place from which it had issued. Generations passed away and the powers of electricity, as we are beginning to recognise them, remained unknown: the matter continuing more one of curiosity than practical utility.

But the philosopher's toy of one age may be the trusty servant of the world a generation later, and watching the movement of pith balls and bits of paper has given us the electric telegraph of our day. The first practical step made in the application of electrical force to remunerative mechanical ends was due to Michael Faraday in 1830, and yet it was a poor little thing after all—a mere pigmy effort compared with the giant results of our day: it amounted to no more than showing how a magnet could be made to produce an electrical current in a contiguous strand of copper wire. The important point in this experiment is that it is not the vertical magnet that produces, in the small suspended needle, the disturbance, but it is the *movement* of the vertical bar magnet that moves the suspended needle, which only swings when the bar magnet is dropped into the coil or taken out of it. The electrical current is not the cause of the movement, nor is it the primary source of that movement: it is only the means of its transmission from the place where it originated to the place where it takes effect: it is simply a case of the conversion as well as of the transmission of force. The mechanical impulse is first of all transmuted into an electrical current, and then with more or less completeness reconverted into mechanical effort, when the produced movement is set up: in short the muscular effort of the operator's arm, by which the bar magnet is lifted or dropped into the coil, is absolutely and essentially transformed into the propagation of an electrical effort: that is, into an electrical current along the wire. It was Michael Faraday's arm that moved the needle at the end of the wire. I need hardly remind the reader that an electrical current is only energy in another form: in other words, electricity is nothing more nor less than one of the forms of energy, and heat can be converted into electricity, as can chemical action. This, therefore, means that to get a large amount of electro motive power available for human purposes either coal must be burnt, or wind used, or the energy of the tides and rivers economised and transmuted. But before coal can be burnt it must be worked, brought to the surface and perhaps conveyed long distances, and then transmuted into electricity: much of this costly labour would be saved if something cheaper, more abundant, and practically inexhaustible, like the tides, could be found, and it is to the tides I am convinced that, when certain mechanical impediments are overcome, we shall look for our motive power.

Two years after Faraday's discovery M. Pixii, a Parisian instrument maker, used a horse shoe magnet, mounted vertically upon its loop or curve in such a fashion that it could be caused to revolve in an upright position round and round. He placed two copper coils, each containing a bar of soft iron, standing vertically above the horse shoe magnet, with the lower end of each just fixed above the horse shoe magnet. By means of clever contrivances a very serviceable current was obtained from this ingenious instrument. His machine was practically the forerunner of the innumerable machines for the so called conversion of electrical currents into mechanical power, which have since that remote time—scientifically—been called into existence. Subsequently to Pixii's time the most important steps in the improvements of the apparatus were, "first, that a pair of electro magnets, with their engirdling coils, were made to revolve in close apposition to a suitable fixed permanent magnet: and then that a considerable number of electro magnets fixed upon the circumference of two circular bronze places were driven, the one following the other in rapid succession, between the poles of two large permanent magnets." The first modification we owe to Saxton and Clarke, while M. Alfred Niaudet gave us the second. The Alliance machine, constructed by M. Noblet at Brussels, memorable as being the first magneto electrical machine used to produce illumination in a lighthouse, was an extension of the Niaudet system.

In 1854 an important improvement in the construction of magneto-electro-motor machines was introduced by Messrs Siemens and Halske of Berlin: they found that even augmented currents could be produced when the coils of copper wire were turned lengthwise, over and under the revolving axis, instead of being bound spirally across isolated bobbins or cores, and so arranged as to be transported bodily past the stationary magnets, It would be difficult to over estimate what the world owes to the Siemens family of Hanover, London, St. Petersburgh and Berlin in the application of electricity to motor purposes, and the recently published life of Sir William Siemens is an inexhaustible mine of information on this point. Although scientific discoveries are often made simultaneously in widely different places, there seems good ground to credit the Brothers Siemens with a leading part in the following improvements and inventions—the galvanic process for silvering and gilding, anastatic printing, the insulation by means of gutta percha of telegraph wires, the construction of submarine mines for purposes of warfare, the laying of underground telegraph cables, the block system of railway signalling, the adoption of porcelain insulators for telegraph wires, the regenerative gas burner, the construction of the telegraph cable ship *Faraday*, and the erection of the first electric railway—surely a goodly list of contributions to scientific progress.

In Sir William Siemens' address, as President of the Iron and Steel Institute, in 1877, he spoke confidently of the near approach of the time when motor power would be transmitted by means of the electric current, and he added that he believed that a three inch copper rod might be made to carry the energy of one thousand horse power thirty miles from a large waterfall, or other natural source of moving impulse: I too believe the same, but there is much to do before even this is accomplished.

To utilise electricity on a vast scale to do the main part of the work of such a community as ours the amount of electro motive power needs to be enormous. A part of the current is lost in overcoming the resistance of the transmitting wire, and a part in doing the work for which the apparatus is designed: there is always also some absorption in waste, the friction of the machinery has to be overcome, while the electrical state or disturbance has to be got through the wire, hence the temperature of the transmitting wire is invariably raised during the passage of the current, this heat is generated out of the current, and is therefore waste or loss: it is a portion of the original force put into the primary machine by steam power or waterfall power reconverted into heat. Unfortunately this heating of the wire is a positive increase to the resistance in transmitting the current. To obviate this Sir William Thompson proposed to construct the conductor in the form of a hollow wire, or rather of a large tube containing cold water. This heating of the wire is one of the drawbacks to the economical transmission of the electrical current to which I have referred. And it seems to me that the direction in which advance will be made will be in so arranging matters, how I do not pretend to tell, that the wire shall not be heated, or possibly in the utilisation of the heat evolved

during the passage of the current. Another drawback is that the wire has to be greatly increased in sectional area when the current is transmitted a long way; in other words, if the distance is increased six times, the sectional area of the wire needs to be thirty-six times as large, that means a ruinous increase in the weight and cost of the material: here again advance is certain and we cannot doubt that the untiring energy of investigators and discoverers will some day solve the difficulty, so that electro motive power will be transmitted vast distances with little rise of temperature, and with no formidable addition to the sectional area of the conducting wires. The steam engine faced difficulties apparently more formidable, and overcame them, and electricity, the future ruling motive power of the world, the most powerful and convenient servant man has at his command, will overcome all obstacles, and be available for everything to which its wonderful powers can be applied.

The advantages of the electric current are obvious: the electric conductor can be brought round the sharpest corners, and carried through the most private rooms, without inconvenience: there is nothing to give way or burst *en route*. The same circuit, which can be tapped to work heavy machinery, may also move a sewing machine or a knife cleaner. In many manufacturing operations electricity will undoubtedly before many years play a marvellous part: in Scotland electrical power from a waterfall has been transmitted a mile and a half: it will be applicable to dredgers, which could be reduced in size, and so made lighter, and which could be worked from a central motor, so as to be applicable to smaller channels than at present. The success at Craigside, the seat of Lord Armstrong, where a waterfall, as I have said above, provides electro-motor power to light the house and to drive the saw-mill three-quarters of a mile away, is an earnest of the time when the machinery of Birmingham and Wolverhampton will be driven, and the streets and houses of those grimy towns will be lighted by electricity, and they will depend upon the tides of the Severn for their motive power, and when London itself may look to the same vast estuary for its supply of light and mechanical power.

Another question must detain us a minute, as it is of more than passing interest: a current may have high tension and small amount, or low intensity and large amount: to compare small things with great, we have a parallel in running water: we may have a large amount of water flowing slowly with a small fall, or a small quantity descending from a vast height with immense rapidity—the sluggish current of a fen country river or the lightning like velocity of a lofty waterfall. Now the possible work or potential energy of 1000 pounds of water falling one inch is the same as that of one pound descending 1000 inches. The electrical current is constantly observed in both these forms —a small amount in a high state of tension, or a large quantity in low tension. The Voltaic current issuing from a Voltaic battery of a small number of cells may be compared to the sluggish river, while the electric spark corresponds to a waterfall.

The subdivision of electric currents for purposes of mechanical work has been accomplished, although at present, with our imperfect means, every step in their subdivision and distribution means increased resistance and economical loss. Alexander Siemens thinks that setting the primary generator to charge the secondary batteries of M. Faure will be the best course. Sir William Thompson recommends the utilization of windmills for the storing of Faure accumulators, and indeed until perfect methods of transmitting the current are devised I fancy that the use of accumulators will be found to meet the difficulty, but almost any day we may hear of improvements in insulation and transmission.

Professor Sylvanus Thompson stated at the Society of Arts, several years ago, that the lamented Clerk Maxwell having being asked just before his death which he considered to be the greatest discovery of late years, replied, "the discovery that the dynamo-electrical machine is reversible," and he continues that were Clerk Maxwell still living, and to be asked the same question to-day, he would answer, "that the Voltaic battery is reversible," "for adds Sylvanus Thompson," the reversibility of the Voltaic cell, instanced in the Faure store battery, is the counterpart and complement of the reversibility of the Gramme machine, for while the one has solved for us the problem of electric transmission of power, the other has solved for us the problem of the electric storage of energy. Accumulators are an almost necessary feature in any scheme to utilise the intermittent force of the tides. Probably the present accumulator bears as much resemblance to the accumulator of the future, as a glass bell jar used in chemical experiments does to the gasometer of a city gas works, or as James Watt's first model steam engine does to an Atlantic Steamer.

Mr. Siemens believes that at sea the electrical transmission of power has no useful application, the machine driven ship having to carry the whole of its origination of power within itself. I grant that colliery proprietors may still take heart as far as this goes, but surely the time will come when electricity will be applied to the propulsion of ships. I at least believe in its possibility. No doubt when the stationary steam engine was *un fait accomplit*, no one suspected that long strings of carriages would be driven, and ships propelled by modifications of it. Should I live forty years longer I shall hope to see greater marvels than ships driven by electro motive power.

Electricity has already done wonders and has been used in a thousand ways: it has ploughed land with a double furrow and thrashed wheat: no spectacle is more astonishing than to see sawmills, lathes, and sewing machines at work driven by a small bell wire running down from the ceiling of the workshop. The electrical agent has no inertia to overcome, no weight of its own to move: it is an imponderable sprite; going round corners without loss, pursuing the most tortuous and the most direct paths with equal indifference: it is free from danger and without smell, in short, it is the great motor power of the future, the greatest wonder, our own bodies excepted, within the cognisance of our senses.

Professor Sylvanus Thompson has pointed out that the construction of only a few yards of embankment, in the neighbourhood of Bristol (probably he means in the Avon), would provide a tidal basin with a rise and fall of twenty-three feet, which would amply suffice, turned to mechanical uses, to charge every year ten million Faure accumulators and to raise twenty billions of pounds one foot high. One-tenth part of this energy would be sufficient for the permanent lighting of Bristol. He further calculates that one-fifth part of the tidal energy, now running to waste in the estuary of the Severn, near Bristol, where the rise and fall exceed twenty-three feet, would be enough, transmuted into electricity, to light every city and to turn every loom, spindle, and axle in the United Kingdom. Professor Perry, in some brilliant comments on certain of Professor Joule's experiments, goes farther. He prophesies that

before long we shall have great central stations, perhaps at the bottom of coal mines, where enormous steam engines will drive immense electrical machines. Along every street he believes wires will be laid, tapped into every house, much as gas pipes are now, and the current will be passed through little electric machines to drive machinery, ventilate houses and rooms, replace stoves and fires, and to work everything required in the household economy from mangles, sewing machines, and barbers' brushes down to apple-parers; and he goes on to add that with properly constructed machines the energy of Niagara could be converted into electrical power, and be transmitted to New York, there to be used for everything to which human labour is now commonly applied, and to much for which human strength is inadequate. Sir Frederick Bramwell prophesies that in less than fifty years the steam engine will be obsolete, and will be replaced by more powerful and convenient machines driven by electro-motor power; and I, for my part, feel sure that this great engineer has not let his imagination run away with him. Nor is his the baseless vision of a heated imagination. Are not engines, tram-cars and railways successfully and economically worked by electricity, and, only the other week, Dr. Samuel Hyde, of Buxton House, Buxton, showed me a small engine at work, lighting the whole of the vast establishment, of which he is the resident physician, with a soft, soothing, but withal brilliant electric light, while Faure's accumulators were being charged in large numbers for Sunday use by the surplus energy of the machine, which also worked an elevator. It is a sad coming down to leave the wonders of electricity for discoveries that in comparison seem commonplace in the extreme.

Coal tar, which has given us saccharine and many dyes of surpassing brilliancy and permanence, has also given us vanillin, which is displacing the older and the more familiar, though not more useful vanilla. I am not sure that those remarkable colours and flavours exist in coal tar ready formed; possibly the processes to which the latter is subjected lead to the building up of valuable compounds—this is a matter that would be hard to explain to readers ignorant of chemistry, though intelligible to the better informed. If, as I suspect may be the case, the manipulation of the chemist leads to the formation of many fresh compounds, there seems to be a good chance of increased economy in their preparation, and further advances in chemistry will probably facilitate and cheapen their preparation. Will my readers wonder if I repeat at somewhat more length that a young man, wishing for a scientific career affording greater promise and scope than any other, must choose the field of chemical research? Labour can hardly be misapplied there, and vast fortunes may be built up such as the man of letters, the physician and the minister of religion can only see in visions of the night. I am informed, apparently on good authority, that in some of our great northern towns scientific chemists are reaping a golden harvest from labours, which in addition to their scientific interest are eminently practical and remunerative. I am not a chemist, and my attainments in that line would be laughed at in chemical circles, but I know enough to be sure that the world will, in the long run, owe far more to chemistry than to medicine and surgery, indeed it might possibly dispense with doctors, but as for chemistry, born only a century ago, the feeble infant of our childhood, it is growing by leaps and bounds, and making its influence felt in all occupations, and to the remotest ends of the world.

In conclusion, let me say something about the natural history of cocaine, that invaluable drug which, with meteor-like rapidity, has come into common use. It has the singular property of deadening mucous membranes, so that operations on the eye can be carried out without the necessity of bringing the whole system under the influence of an anæsthetic, as was till recently necessary when chloroform and other members of that class were alone available. A strong solution of cocaine is applied to the mucous surface, and in a few minutes sensibility is temporally gone, and the most serious operations are practicable. I have been repeatedly assured by patients that they have felt nothing, and that they did not experience any discomfort even in long and tedious operations. Cocaine is a valuable drug for internal administration, and apart from operations, is most soothing to the surface of an inflamed eye; indeed it saves many an eye that would otherwise be doomed. My old school-fellow and fellow-student, Professor Priestley Smith, of Birmingham, considers that the most striking advance in ophthalmic surgery in modern times has been the introduction into common use, by Kohller, of Vienna, of this elegant preparation. But I must not forget that this drug, though it has only just come into use, and though three years ago it was totally unknown to the general public by name, and to the medical profession as a therapeutic agent, is one of great antiquity, and to the student of foreign lands and peoples was familiar enough by repute. When the Spaniards landed in South America they found the natives of the tropical valleys of the Eastern Andes, or rather of Bolivia, Peru, and Brazil, in the habit of chewing the leaves of a plant, now scientifically called Erythroxylon coca, the latter being a corruption of "khoka," which, in the Aymara language, means *the plant*. Not only did the Indians chew it, rolled into a ball and called "acullico," but with every fresh supply they put into their mouths a little unslaked lime on the end of a bit of wood, which, having been moistened, they had dipped into a lime flask. The Indian of America is a strange compound of melancholy and fortitude. He vanishes before the white man, though generally displaying conspicuous courage and determination in the conflict. He delights in dreamy contemplation, and to this may be ascribed his passion for tobacco and coca, to both of which he is peculiarly addicted. It is the custom to give the people of the districts where coca is indigenous or cultivated a few moments' rest, while they chew their favourite narcotic, to the enjoyment of which absolute repose and absence of pre-occupation are essential. In this way the Indian gets through an ounce or an ounce and a half of coca leaves in twenty-four hours. The time given to the consumption of coca is called "chaccar," and employers of labour find it an advantage to allow their workpeople to have this enjoyment at stated periods. Von Tschudi, speaking of the Indians of the Peruvian Andes, and his description applies fairly accurately to all members of the Red Skin Race, remarks that in their domestic relations they are unsocial and gloomy. Husband, wife, and children live together with little appearance of warm affection. Children approach their seniors with curious timidity, and whole days sometimes pass without the interchange of a word of kindness between them. When not engaged in out-door work the Indian sits gloomily and contemplatively in his hut, chewing coca, and brooding in silence over reflections that seem to offer little that is cheering. It has been asserted that coca diminishes the need for food, and increases the power of surmounting

great heights, and I remember reading, several years ago, some excellent papers by the late Sir Robert Christison of Edinburgh, on this subject, in which he very powerfully described the marvellous improvement in his power of breathing easily, in ascending lofty hills, whilst he chewed coca leaves. Coca, therefore, is not a new thing, except as regards its introduction, or rather, that of its active principle—the hydrochlorate of cocaine—into the armoury of the modern scientific surgeon. But its properties were such that when once recognised, it could not be long before it came into common use for medical purposes. At first the exorbitant price of the alkaloid repelled medical practitioners, as much as four shillings a grain being asked and paid—in other words, nearly £100 per ounce. That soon fell to half the price, then to threepence the grain, and now I believe it can be got at less than £2 per ounce, and no doubt it will fall still lower when more freely cultivated for the European market. The history of coca is that of many other drugs—known at first to a few people, and confined to limited areas, then described more or less intelligently by some learned visitor, and after a time introduced into all parts of the world, and, finally, applied to legitimate uses, adding to the conveniences and pleasures of life, and from a curiosity becoming the prized possession of millions.

LA TREPANACIÓN EN LA EPILEPSIA.

By Dr. Enrique de Areilza,

hospital de trianon, viscaza.

An abstract of a remarkable paper on "Trephining in Cases of Injury to the Skull" was given in The Provincial Medical Journal of May, 1887, *et seq.*; and amongst the twenty-five illustrative cases two were of epileptics, in which the disease was caused by depressed fracture, and a cure effected by the operation. In the last current number of the *Revista de Ciencias Médicas* two more recent cases are narrated, and, although in one only was the operation successful, both are of much interest for diagnostic and surgical reasons.

Dr. de Areilza tells us that there has been no cessation in the appearance of splintered skulls (*cascos hecho pedazos*) in the wards of the hospital under his care, furnished by the workers in the neighbouring iron mines; but, he modestly adds, after reading the brilliant results obtained by Championnière, Victor Horsley, and Macewen, in the same field of surgery, he cannot again refer to them. And the more so, as it is now clearly demonstrated that of all operations, that of removing a disc of healthy bone, or elevating depressed fragments from the skull, is the simplest and safest, and that the *dura mater* has shown itself to be the most tolerant and long-suffering of serous membranes if only reasonable precautions be taken when cutting into or otherwise interfering with it. Championnière lately gave an account of twenty consecutive cases of trephining, and amongst them of six in which the operation was performed, and with complete success, solely for the relief of severe headache.

In cases of idiopathic epilepsy the value of the procedure is still *sub judice*, and every case which can throw light upon its usefulness therein is of interest to the profession. The first in the present paper is an example of the dilemma referred to by Macewen at the recent Glasgow meeting of the British Medical Association: Given an inter-cranial growth which causes severe tetanic convulsions by its presence, but the removal of which would lead to incurable hemiplegia, should one operate? Which is to be most deprecated, convulsions or paralysis? But, are we quite sure that the second premiss is unassailable? may not some reparative or substitutional action in the brain restore the lost function? The answer in the affirmative is given by the results of the operation itself in the first of the following cases, and justifies to a great extent the daring, although in the main unsuccessful, operator.

Case 1. *True epilepsy commencing in convulsive movements of the left arm. Treated by extirpation of the motor area on the right side.*—Pedro Lara Pino, a labourer, æt. twenty-nine, in consequence of a severe fright (*una impresión moral terrorífica*) in 1881 had an attack of acute mania, with tetanic convulsions, lasting two days. A month afterwards the first epileptic attack was noticed, and from that day forwards the fits have constantly recurred, gradually increasing in frequency and force until they reached from twenty to thirty in the twenty-four hours, and the unfortunate man was reduced to utter helplessness. He had been under treatment of the most varied character without any relief whatever. The attacks commenced by a feeling of formication in the left arm, followed by convulsive movements; then the left leg was affected, with the muscles of the face, and the convulsions became general. Their duration was short—from one to two minutes. There was complete insensibility for the time, and no recollection of their occurrence afterwards. In the intervals there was constant pain in the right parietal region, most intense at the level of the centre of the fissure of Rolando.

It was decided to expose and excise the whole of the motor area at this spot on the 23rd of November, 1887. There was, as had been observed in the previous cases, great difficulty in the administration of chloroform. As soon as insensibility had been reached convulsions set in, with so much interference with respiration that death from asphyxia seemed imminent. The inhalation was stopped, and resumed several times with the same result; then a third of a grain of morphia was injected, with some effect, and amid alternate choking and convulsions the operation was proceeded with. It occupied one hour, and during that time nearly eight ounces (120 grammes) of chloroform were expended with very imperfect results.

The motor area was carefully marked out on the shaven scalp, and an incision made through it to the bone in the direction and length of the *linea Rolandica*; this line was crossed at each extremity by two shorter at right angles and the flaps reflected. The trephine was applied on each side of the centre line, commencing at its second fourth, and then upwards until—the intermediate horns being cut away with bone forceps—a space five centimètres by four and a half was obtained. The opening followed the oblique direction of the line, and in order to expose the whole of the implicated area, the trephine was again applied higher up; but on lifting the disc of bone, a torrent of blood showed that the superior longitudinal sinus had unfortunately been sawn into. The pulse fell instantly, and so low that the patient was nearly dead before the hæmorrhage could be stopped by re-inserting the plaque of bone, and retaining it by a bandage. However, he still lived, and the operation was proceeded with. The *dura mater* was incised and turned back as far as the edge of the opening, which laid bare the ascending circumvolution, which appeared to be perfectly normal and healthy, nor did free exploration of the area beneath with a long, fine trocar yield any evidence of

disease. With a sharp spoon the grey matter was then sliced off to nearly the depth of half a centimetre from the surface of three-fourths of the frontal ascending and half of the parietal ascending lobes; it weighed scarcely four grammes. The cut surface became of a blueish tint, and bled very freely; this loss was checked by irrigation with a cold 4 per cent. phenol lotion. Then a stout drainage tube was inserted, the scalp flaps re-united by metallic sutures, and the wound covered by carbolic gauze and a pillow of tarred sawdust. After the operation the exhaustion of the patient was extreme. Several subcutaneous injections of ether were needed before he recovered consciousness, and a long stay in a hot-air bath to keep him alive.

Immediately the decortication of the motor area was affected complete hemiplegia of the left side was evident, with slight ptosis; the latter was, however, only transitory. On the second day the wound was perfectly healthy; there was still complete paralysis, *but there had been no convulsion whatever*, and the patient was quite comfortable. The next day the drainage tube was removed, and the wound was rapidly healing; but it was noticed at the same time that there was some tonic contraction of the left arm and leg. There were also some automatic movements of the same limbs which, to some imperfect extent, imitated those voluntarily made on the opposite side, but the patient clearly had no control whatever over them, or, as he himself said, the more he tried to make them move or be still, the less they obeyed him. By the seventh day the wound had all but entirely healed, and there had been no more marked convulsive movements. The next morning, on awakening, the man found to his great satisfaction that he could slightly move the fingers of the left hand, and then the arm itself; there was also much more voluntary power in the foot and thigh. But there was a singular psychic tension in these restricted movements: the man had to *will* them for some moments before the limbs slowly obeyed the mandate.

He was then put under electrical treatment, and by the end of December could walk fairly well with the aid of a stick, but he had little use in his fingers. But, unhappily, on the eleventh day after the operation there was a well-marked epileptic attack, and in a short time the fits had resumed their old frequency and severity—it had failed utterly.

Case 2. *Fracture and depression of the frontal bone—Hemiplegia—Consecutive epilepsy.*—Manuel Larena, a sailor, æt. thirty-eight years, a hard drinker, but tolerably healthy, was struck on the right side of the head by the boom of his vessel whilst at sea, on the 19th of May, 1885. He was not stunned, and felt but little pain; the wound was plastered over and ice applied, but the injury to the bone was unnoticed. However, twenty-four hours afterwards, hemiplegia set in, with complete paralysis of the left side, the face alone escaping. The man took to his bed, and obstinately remained there for thirteen months. About four or five months after the accident there was a slight epileptic attack, followed by many others. In each the aura was felt as an itching in the left nostril, sometimes followed by bleeding, then contractions of the facial muscles followed, and finally general convulsions, both the paralysed and the sound side being equally affected. The fits happened three or four times a month, but oftener when the man had been drinking.

He came to the Trianon Hospital in August, 1888, and, on examining him, Dr. de Areilza found the scar of the old wound with a slightly marked depression of the bone, it was about five centimetres in length, three from the bi-auricular line, and two from the median. It was approximately over the middle of the first and part of the second frontal lobes; quite firm and insensitive. The paralysis of the lower limb was not complete, some feeble locomotion being possible, but the arm and hand were quite useless. The muscles reacted well to electrical stimulation, but were much wasted. The most careful examination of the skull, however, revealed no sign of injury over the motor zone. It seemed to de Areilza, nevertheless, better to operate at this spot, so the bone was exposed by a semi-circular flap over the region of Rolando and four discs removed, producing an ample rectangular space. The *dura mater* was reflected to the same extent and the brain examined. It seemed to be perfectly healthy; there was no adhesion between it and the meninges, and the bone was of normal thickness. This being the case, the pieces of the skull were replaced and the scalp incised downwards and forwards so as to expose the old depressed fracture. The trephine was applied here three times; the middle disc was found to be greatly altered, much thickened and perforated with holes and channels as if it had been affected with destructive osteitis; it had also a smooth depression in its centre in which lay a small fungoid growth, springing from the *dura mater*. The two other discs were solid and greatly thickened, so much so, that those from over the motor area being but four centimetres thick, these were more than seven, and extremely hard. The little growth was cut away with the portion of the membrane at its base; the *dura mater* was somewhat thickened and adhered to the brain, but beyond this there was nothing abnormal to be seen in either. This terminated the operation; the flaps were replaced, but no drainage tube was used. There had been exactly the same difficulty in the chloroforming as in the former and previous cases.

By the sixth day the wound had firmly healed without any complication. As for the results of the operation it would be premature to express any opinion at present; cases of paralysis and epilepsy of so long standing require extended subsequent observation to enable one to report the results faithfully. Up to the present time all has gone well; in two months there was but one slight fit, which lasted only a few seconds, and was confined to the paralysed side. The hemiplegia is also lessening; the leg is especially better, and there is great improvement in the movements of the hand. But the patient himself is the greatest difficulty, he will not submit to the electrical treatment, and his habits are as disreputable as ever.

The two cases differ fundamently, the one was an ordinary example of epilepsy, the other the same disease of traumatic origin. In the first, the severe procedure was adopted of cutting away (but scarcely to its full depth) the grey matter of the motor area, and that it was correctly localised was proved by the induced paralysis of the limbs in which the convulsions commenced, but the results were disappointing and disastrous, the man's condition being distinctly worse than before. In the seconed case no more was done than extirpating a little growth no larger than a barley grain, and removing some bone which pressed but slightly upon the brain, but the effects seem to promise all we could desire. In this case, any severe operation would have been unjustifiable. But in the first example there was a poor labourer, reduced to utter helplessness and misery by thirty fits a day, and no remedy which offered any chance of relief seemed too desperate for trial. Now the results

which Horsley has obtained justify us in opening the skull and examining the brain in this disease; but, on doing so, nothing abnormal was to be seen, and even puncturing the motor area gave no more indicative results. Under these circumstances it seemed unreasonable to the author to simply reclose the wound; it is true that he had no authority for proceeding farther; up to that time surgeons had only removed portions of the brain which were manifestly diseased, and none had ventured to cut away aught from its substance which seemed microscopically intact, but it appeared to him that the disease might be due to molecular changes within the cells so intimate that the only remedy was their ablation, even although to the eye they had the appearance of being sound and healthy.

Impressed, also, by the teaching of Unverricht that the cause of epilepsy invariably resides in the grey matter of the hemispheres, he removed it from the indicated area with the full knowledge that hemiplegia—probably incurable—would follow, with the conviction that the induced disease would be more tolerable than that he hoped to cure. But the result was a complete disillusion, the pariesis passed away, the epilepsy returned; and it is clear that cerebral topography has not yet reached that perfection which could enable it to guide the hand of the surgeon unerringly to the site of the lesion he is in search of. And this is most instructively shown in the second case: most surgeons would have been content to have removed the depressed bone and cut away the fungoid growth; but Dr. de Areilza had such perfect confidence in the mapping of the motor areas, that he only did so after he had convinced himself that the normal place was really not the site of the mischief.

The author does not refer to the question, if removing the grey matter to a mean depth of half a centimetre can be said to be effectual, its thickness is certainly much greater. Had he excised the whole of it down to the white fibres, the paralysis would have been more profound, most probably irreparable, but would there not have been a greater certainty of obtaining the end for which the operation had been undertaken? As it is, it seems that as soon as the surface wound had healed, the portion of grey matter left had been able, although imperfectly, to carry on the work of the whole; any replacement of the lost cells being out of the question.

The scarcely to be regretted death of the patient, Pablo Pino, four months after the operation, gave an opportunity for tracing the history of reinserted bone: one disc was replaced, we have seen, as the readiest means of checking the hæmorrhage from the disastrously invaded superior longitudinal sinus, it was left there, not without considerable misgivings as to its ultimate behaviour—the possibility of its death and consequent suppuration being one contingency—but all turned out well, the scalp healed over it, and to the touch it seemed as if firm bony union had taken place. But this was not the case: at the *post-mortem* it was found that the bone had been tolerated, not welcomed; it was firmly attached externally by a fibrous growth, but within it was quite free; it had the pinkish colour of living bone, but it had been riddled into trabeculæ; its life had been preserved by the pericranium, which had also formed its attachment to the skull, but its blood supply would seem to have been too restricted to permit ossious growth. However, it made a far better covering for the brain than the tough, but elastic growth usually left to be formed, with the frequent vertigo and hemicrania in its train, and the plan with aseptic precautions is one well worth following.

G. F. CADOGAN-MASTERMAN, M.D.

MONTHLY REPORT ON NEW PREPARATIONS, FOODS, DRUGS, INVENTIONS, ETC.

Bouillon Fleet.—Messrs. Fleet and Co., Fenchurch-avenue, London, have after considerable pains succeeded in producing an excellent preparation suitable for ordinary household consumption, for invalids and sick persons. It is a highly concentrated food, with pleasant flavour and taste, and readily miscible with water in varying proportions, according to the strength desired. Too many of our beef extracts advertised are simply condiments, giving a relish, but not possessed of much food value, and we are pleased to have an addition in the shape of a bouillon, which fulfils all the conditions desirable. The samples we have tried have given perfect satisfaction. It is a nutritious and concentrated food.

Rowntrees Elect Extract of Cocoa.—Cocoa, well prepared, and with a proper flavour and aroma, is one of the most nourishing and economical of diets. Unfortunately, cocoa is very much adulterated, and when not adulterated is mixed with sugar, potatoes, starch, etc., which make a cup nauseous and thick. Rowntrees cocoa is a pure unadulterated extract; has a fine delicate flavour, and possessing all the nutritious ingredients for which cocoa is noted.

The Carbon Chemical Cone Company.—We have already alluded to the original preparations issued by the above-named company, and we may briefly recapitulate what we established in reference to their cones. 1. The cones, which are filled with scent, as white rose, heliotrope, sweet briar, etc., etc., are most elegant accessories, not only for the sick room, but for ordinary use for the perfuming of rooms; the aroma of the individual scent may be distinguished. 2. We established that the disinfecting cones charged with capsules of carbolic acid, carbolic and iodine, etc., possessed powerful deodorising properties, under conditions, as where a close stool has been used, the smell of which is completely neutralised by the burning of a cone. This class of cone we have also used for the disinfection of rooms which have been occupied by scarlatina patients, using for this purpose for a room of medium size one or two cones. The sulphurous acid cones we have tried for the disinfection of some rooms which had been used by children suffering from whooping-cough. We do not remember the name of the writer who highly recommends sulphurous acid and sulphur fumigation for whooping-cough. That this system is one to be recommended, we have the strongest evidence, and by means of the cones we have a ready method of charging a room with varying degrees of sulphurous acid vapour, or if necessary, with carbolic vapour, depending on the number of cones used. For the disinfection of a room with carbolic or sulphurous acid, the windows should be closed, and one or two cones lighted, the children being moved during the process into another room. There is a great choice in the list of disinfectants, and those who do not like the smell of carbolic can use a cone in which the carbolic is combined with lavender or thymol. A caution we must give, when the cone is lighted and placed in position, it should not be meddled with or

taken up, and this caution is especially necessary with the cones made with chlorine, as the chloride of ammonium cones. If stirred a cone may explode, and cause a little temporary alarm. One of the strongest and also one of the most agreeable of the disinfecting cones is the camphor carbon, which will be found highly useful by nurses in purifying the room of a fever patient. 3. The medicinal cones are intended to saturate the atmosphere of a room, so that the patient may breathe an air charged with medicine, and these cones are especially indicated in the treatment of asthma, bronchitis, pertussis—the only diseases which and we have been at present able to employ them. The treatment of pertussis is unfortunately largely empirical, we have to fall back upon experience for guidance. It appears to be established that pertussis may be palliated by the use of disinfectants, as chlorine, carbolic, eucalyptyne, and bromine. An old plan of burning carbolic acid on a heated shovel has long been in vogue, and excellent results are reported by this method. The cone gives us a more elegant and easy method of applying medicated vapours, which can be breathed by children suffering from pertussis. We have tried for this purpose the bromo-eucalyptol cone, which is one of the most agreeable and efficient of the series, and which does not irritate the sensitive mucous membrane as sulphurous acid and carbolic acid do. In bronchial asthma we have used the vapour of the pinus sylvestris and chloride of ammonium, and are able to speak favourably of their action. The chloride of ammonium cone gives off very dense fumes, and one cone is sufficient to fill an ordinary sized bedroom. We shall publish another report from our chemist, which will enter more particularly into the volume of gas or vapour given off, so that we may know the exact air space one cone will fill. We are convinced that in these cones we have a ready and reliable method of applying attenuated medicinal vapours, and that their future development and adoption by practitioners will follow upon the more exact knowledge of their dynamics.

The Swiss Milk Company's Flora Alpina.—This is a sweetened and pure compressed milk extract, which is guaranteed to be prepared in Switzerland; it is an agreeable preparation, possessing all the properties claimed for it by the makers.

Pearl-Coated Pills, etc.—Coated pills which will readily dissolve when swallowed, *and not pass out unchanged*, are now in reach of the profession in London and the provinces. Messrs. John Richardson & Co. have made a speciality in their manufacture of pearl-coated pills, and testimonials as to their value have been received from all parts of the world. A town depôt for these pills and other specialities has been opened at 6, Great Russell-street, Bloomsbury, a few doors from the Oxford-street end of Tottenham Court-road, where the specialities of the firm can be seen and purchased.

Reviews.

Ophthalmic Practice. By CHARLES HIGGENS, F.R.C.S. Lewis's Practical Series.

THE wants of students and general practitioners are now-a-days—thanks to the watchful care of enterprising publishers—amply provided for. Each month furnishes its quota of hand-books, in whose prefaces the words—practical, brief, concise, frequently occur, expressive, as we take it, usually of the author's aims, occasionally of his apologies. The book before us is an example. We think the publishers have been singularly fortunate in their selection of Mr. Higgens for the task they have assigned to him. It is now more than ten years since his little work, entitled "Hints on Ophthalmic Out-patient Practice," appeared, and its value has been sufficiently attested. In the present comparatively large work similar excellencies are manifest. Its style is markedly didactic. The reader is not asked to weigh the comparative merits of various operations, nor is his mind confused by conflicting theories; but the author states his own views—which are always definite, and what is more important, usually correct—in such a manner that they are evidently not the outcome of a rash resolve, but rather the fruit of a large and matured experience. This we conceive to be of the greatest moment, and best fulfils the purposes for which the book was published, *i.e.*, to be of service to those practitioners who in the chances and changes of their daily work most of all require a safe and sure direction to guide them in emergency. It must, however, be admitted that should the critical specialist approach the work from his particular standpoint, he may be pained to find the omission of some cherished theory, or recommendations to some line of practice contrary to his own views. A brief example or two will suffice:—In speaking of optic neuritis, Mr. Higgens uses the old, almost obsolete, designation of "choked disc." This might be considered an error of some gravity, as the name implies a pathological process which has now but few supporters. Considering the connection between the eyes and certain cerebral conditions, we should have expected a more lengthy description of hemiopia, the one furnished being scarcely more full than would be found in an ordinary dictionary. The directions for the after-treatment of cataract extractions we think require emendation, there being no benefit derivable from constantly wetting the lint. Nor is it to our minds the best policy to postpone examining the eye operated on for a week. In conclusion, we believe that anyone who requires a book on ophthalmology, wherein he will find plain direction, good counsel, lucid definition—the whole free from ambiguity, either of terminology or expression—cannot do better than select the work we have thus briefly noticed. CHARLES G. LEE.

Clinical Lectures on Diseases of the Urinary Organs. By SIR HENRY THOMPSON. Eighth edition. London: J. and A. Churchill.

"THE whole of these lectures have been thoroughly revised. Much of the text has been re-written, and considerable additions have been made, with the object of conveying, in clear and simple language, those views, which, after long enjoying an unusually wide field for practice and observation, appear to me to be the truest and the soundest respecting each topic he had considered." This quotation is taken from the preface to the eighth edition, and we can verify its accuracy. The lectures, preserving the colloquial style in which they were originally presented, are enriched by the latest experience of the writer and the latest advances in operative measures for the relief of stone or tumour, and for all the emergencies which may occur in connection with urinary diseases

The new edition is profusely illustrated, whereby its value to the student is very much increased, making it the most complete as well as the most concise text-book in any language. Sir Henry Thompson possesses the art of condensation and of putting things clearly, and hence his great success as a teacher and lecturer. He has another gift of a charm of style, which owes its chief attraction, perhaps, to its very simplicity. It is to the credit of English medicine that this work has been translated into French, German, Spanish, Italian, and Russian, and is employed as a text-book in most of the medical schools of Europe. It needs no better endorsement.

Intestinal Diseases of Infancy and Childhood. By A. JACOBI, M.D. Detroit, Mich.: George S. Davis. 1887.

THIS book is quite an exception to the usual unprofitable results of writing on the special diseases of children. The author shews that in the first year of life the stomach and the intestines are the sources of a high death-rate amounting to forty per cent., whereas in the second year only nine per cent. are due to digestive troubles. It is clear that hygienic rules for infants concern the digestive organs mainly, and hence an account of the physiology, hygiene, pathology, and therapeutics of the infant's alimentary canal forms an unusually interesting and instructive volume. An experience of more than a third of a century justifies the author in attempting to diminish infant mortality by insisting on normal alimentation during the first few months of life; he points out that almost one-half of the infants who die before the end of the first year do so before they are one month old, and that the mortality diminishes with every day of advancing life. The following quotation will serve to give an illustration of the style and practical value of the book.

"How should children be fed, from a spoon, from a cup, or from a nursing bottle? Most certainly from the latter. It alone gives the certainty that the food has a suitable consistency and contains no lumpy ingredients. The accurate removal of lumps and a uniform consistency of the food is analogous, in the child, to mastication in the adult; at least, this is approximately true. The prejudice which is prevalent with mothers and many nurses, that thick nourishment is necessarily nutritious, must be met and opposed energetically. Proper digestion demands, above all, a gradual introduction of the food into the stomach. The use of the bottle is so much the more indicated, as well as desirable, in that when a slight degree of weariness comes on after its use, the infant is naturally obliged to cease nursing."

We refrain from further quotation. The book is one to read; abstracts from it are inadequate. It contains the ripe experience of a good observer, and is likely to be of great value to those who consult it.

R. SHINGLETON SMITH, M.D.

Nerve Prostration, and other Functional Disorders of Daily Life. By ROBSON ROOSE, Esq., M.D., etc. London: H. K. Lewis.

WE believe we are indebted to America for the term, "neurasthenia," or nerve prostration, which is really not a disease, but a condition due to many causes. Oliver Wendell Holmes says that when the nerves are tapped, as by a shock, we cannot measure the loss, as we do with blood loss, though we can see the results in the blanching and weakening which follows from shock. We must recognise that there is in modern life a state in which we have definite symptoms of prostration, brought about by over-work, over-anxiety, and the pressure of competition. Dr. Robson Roose has caught up the popular wave, and rather alarms us by the prolific nature of his pen in producing a work extending over 600 pages.

When we examine the work in detail we can at once account for the size it has assumed, and we find included in his text a number of diseases which have no connection, as far as we can see, with functional nervous disorder. It would be possible by the process of reasoning he adopts to include all the diseases in our text-books under the heading Neurasthenia, because they sometimes occur in persons who are the victims of nerve prostration. However this may be, or however we differ as to the author on the question of the wide spread ramifications of neurasthenia, we are able to thoroughly agree with his therapeutics, and this we consider the strongest point in the book, and sufficient justification for its production. Dr. Roose writes from a considerable experience of this class of disease, so that we can receive his advice with confidence. The work is beautifully printed in large type, so that it is a pleasure to turn over the pages.

A System of Midwifery, including the Diseases of Pregnancy and the Puerperal State. By WILLIAM LEISHMAN, M.D. Fourth edition, vols. i, ii. Glasgow: James Maclehose and Sons.

THIS work has reached a fourth edition, a sufficiently gratifying recognition of its appreciation by students and practitioners, especially when we remember the number of works we have on obstetrics. We approve of the division into two volumes, as a large book is a great evil for the reader, as we found out with the second edition, which was in one volume. On comparing the two we find that considerable additions have been made, especially in the physiological portion, so as to bring it down to the latest views. There are admirable sections on the diseases of pregnancy, whilst the mechanism of labour is admirably explained and illustrated. The author takes us through the various presentations, giving very full and detailed descriptions and excellent drawings of each, and then deals with operative measures. Management of mother and infant receive a due share of attention, and the complications which may occur after delivery receive exhaustive treatment. The work is admirably adapted for the use of the student and practitioner who really desire to equip themselves thoroughly in what forms such an important part of general practice.

A. B.

Hydrophobia: a Review of Pasteur's Treatment. By W. COLLIER, M.A., M.D. Cantab., M.R.C.P.

DR. COLLIER tells us that: "The following short sketch has been written with the hope of making Pasteur's many valuable discoveries, and the experimental evidence and other facts on which his treatment of hydrophobia is based, more widely known to the general public." The reader will find

herein a short but clear statement of Pasteur's investigations and curative measures taken against the silkworm disease, which proved so extensively fatal in the south of France, in 1849. Following upon this we have an account of inoculations which are said to have arrested the splenic fever. The principal point, however, of Dr. Collier's pamphlet is a favourable presentation of Pasteur's treatment of hydrophobia. In a tone of full confidence, the author states that inoculations are now performed upon dogs and rabbits with impunity, which, with absolute certainty, would kill in a few days had not the system been prepared to resist the poison by previous inoculation of weaker and less potent virus. It is nevertheless respectfully submitted that, for the treatment in man, *sub judice lis est;* and that it will be found to have been treated of more strictly in conformity with the laws of scientific enquiry, on previous occasions, in the pages of this journal. W. B. Kesteven, M.D.

Short Notices.

De L'Ozène Trachéal. By Dr. Luc.

Tracheal ozena is a variety of inflammation of the trachea which is usually found to be connected with nasal ozena, although sometimes it is developed independently. The secretion is marked by a peculiarly fetid smell, and a microscopic examination reveals micro-organisms identical with those observed in the crusts formed in nasal ozena. The crusts of tracheal ozena are formed within the trachea. The clinical manifestations are expectoration, especially in the morning, of a thick, viscid, and greenish phlegm, having the peculiarly fetid odour of ozena. This fetid smell persists after the most careful cleansing of the nostrils, and is as marked in the breath expired by the mouth as by the nose. To place the diagnosis beyond doubt the laryngoscope should be employed. Tracheal ozena renders the prognosis of nasal ozena much more unfavourable, as the cleansing of the naso-pharynx fails to remove the fetid character of the breath. The crusts adhering to the tracheal walls may be softened and detached by the inhalation of medicated vapour or spray, but they return at once if the treatment is discontinued. Dr. Luc, in his monograph on tracheal ozena, proves himself to be a careful and painstaking clinical observer. H. R. Hatherly.

On the Vomiting of Pregnancy and Menorrhagia. By John Meredith, M.D. Edin., Medical Officer of Health, Wellington, Somerset.

Dr. Meredith does not, upon the whole, appear to concur in the opinion expressed by Dr. Graily Hewitt, that "the almost universal cause of the vomiting of pregnancy is displacement of the uterus;" he shows, from cases under his own observation, "that inhalation of sewer air, or exposure to noxious unhealthy environment, might be a potent factor in bringing about the ill complained of." Dilatation of the cervix in the case he has put on record, effected the cessation of the symptoms. "Taking all points into consideration, it seems true," Dr. Meredith observes, "that the flexion, in the marked form in which I discovered it, was more probably the consequence of the vomiting than its cause;" an opinion, it may be observed, the contrary to that expressed by Dr. Hewitt, on this point, as quoted by Dr. Meredith. The cases of menorrhagia related by Dr. Meredith are also referred to the unhealthy hygienic surroundings of the patients.
W. B. Kesteven, M.D.

L'Alcohol, Physiologie, Pathologie, Medicine Legale. By Dr. T. A. Peeters.

This work forms a very complete summary of the numerous treatises on alcoholism which have appeared during the last few years. The first part deals with the physiological action of alcohol on the digestion, respiration, circulation, etc. The second part treats of its pathological effects, and, as might be expected, the action of the poison on the nervous system is very minutely described. The third part is devoted entirely to the jurisprudence of alcohol, and the relations between crime and drunkenness and the question of responsibility are fully discussed. Since Dr. Lancereaux published his work, it is the first systematic treatise on alcoholism. H. R. H.

Leçons Cliniques sur les Affections Chirurgicales de la Vessie et de la Prostate. By J. E. Felix Guyon.

These lectures, which were delivered at the Necker Hospital by Professor Guyon, throw a great light on the pathology of the bladder and prostate gland. The author's first lecture is on hæmaturia in retention of urine, and after intra-vesical injections. He lays down certain rules in reference to injections, which are the outcome of a long and extensive practical experience. The lecture on the surgical treatment of tumours of the bladder is original and instructive. Few men have contributed so much to vesical surgery as Professor Guyon, and none are entitled to speak with greater authority. The lectures on diseases of the prostate gland, and on the numerous varieties of cystitis, give clear and concise information which will be of great value to those in actual practice. The work concludes with lectures on acute and chronic prostatitis, and on diffuse carcinoma of the prostatic pelvis. These lectures are intended to form the first of a series of three volumes on the pathology of the urinary organs. H. R. H.

Illustrated Lectures on Ambulance Work. By R. Lawton Roberts, M.D. Third edition, with illustrations. London: H. K. Lewis.

This is one of the most complete works on ambulance subjects we have yet seen, and one admirably suited for those who intend to engage in ambulance instruction. It is too full for ordinary ambulance classes, as it far exceeds the syllabus laid down by the St. John Ambulance Association. The lecturer should, of course, be far in advance of his class, and in Dr. Roberts' work he will find a mass of material to hand derived from different sources, and on perusing it will be able to select what may be suitable for his own class. Dr. Roberts does not confine himself to the St. John Ambulance syllabus, but gives a sketch of ambulance work as carried out in our own army. The illustrations will be found particularly serviceable.

The Provincial Medical Journal,

JANUARY, 1889.

THE support we have received from the profession during the past few years has been most gratifying, and we have to express our indebtedness not only to the members of our staff who have helped to make the paper what it is, but to those members of the profession who have so liberally contributed. We should like to refer individually to some of the articles which have appeared, but this might seem invidious. In order to keep pace with the demand upon our space, the journal has been enlarged to sixty-four pages of reading matter, and in addition we have arranged for the full illustration of any papers requiring it, so that every inducement is offered to subscribers. We have not confined our space for the special use of members of the profession who have an established reputation; we have aimed at inviting contributions from all classes of the profession, so as fairly to represent what is cotemporary medical practice, not in one rank, but in all the grades. We have mingled scientific with practical articles, so as to suit the different classes of readers; whilst in our summaries we have presented a fair *resumé* of cotemporary medical practice in many countries. For some years articles on new remedies have been a conspicuous feature of the journal, and as these have been written by a distinguished member of the pharmaceutical society, our readers can rely upon the accuracy of the descriptions given; while the notes by the same author have given the latest information on all the newest pharmaceutical preparations. In current notes and topics we have alluded to the chief incidents in the medico political life of the profession; while in the leading articles we have dealt with graver subjects affecting our professional interests. We have steered clear of personal reflections in anything we have written, and to this rule we shall continue to adhere. We hope that the arrangements we have made for the year 1889, will meet with the approval of our readers, and we think we can promise them a series of papers from some of the best workers in the profession, so that the standard of the journal will be fully sustained, and it will continue to be worthy of the title which it has assumed.

IT is a curious fact, which is said to have excited the surprise of Dr. SAMUEL JOHNSON, that the inventor of spectacles has found no biographer. The truth is that considerable doubt exists as to the very name of the gentleman in question. Some hold that it was one SALVINO, who died in 1318, while others maintain that the discovery was announced by SPINA in 1285. An interesting article on this subject appeared in an early number of the *Quarterly Review*, from which we have taken some of the following notes. In the year 1826, a treatise on "The Economy of the Eyes" was published by a Dr. KITCHENER, who declared that the only individual incapable of acknowledging the value and usefulness of his book was an optician, who complained that it would have the effect of making the public as wise as the trade. In bringing out a second edition of his work, Dr. KITCHENER begged his readers—if they were capable of any such feeling as that of gratitude—not to lend his book to anybody, but to advise everyone to buy a copy for himself. In 1847 a work appeared "On Vision, in Health and Disease," by ALFRED SMEE, F.R.S. The only modest thing about this production was its price, and even that could not redeem it. The *Quarterly Review* summarily disposed of the publication in these words: "We would advise no one to buy it who has any love for a shilling"—advice not altogether inapplicable to the purchase of certain literary ventures of even a later date. "Those who cry themselves up," sententiously added the Reviewer, "provoke others to cry them down." A more deserving work was that published in 1847, "On Near and Aged Sight and Impaired Vision," by WILLIAM WHITE COOPER, whose wisdom on this subject, however, falls far short of that of the present day. The man who, with or without the aid of books, obtains at the right time the spectacles that he requires, is indeed a happy being. "The haze before him is dissipated, and he seems to gaze upon a renovated world." On the other hand, the misery of the mortal who continues to overtax his vision, has been humorously described as follows: PEPYS returned from the play, his eyes "mighty bad," and recorded that it taught him, "by a manifest experiment," that the candles of the theatre made him sore (what would he have said, poor man, to the glare of more modern inventions!) But his passion "to gaze on the fair, who caused him his care," still brought him back, to gaze on the light that hurt his sight, and there, with the prospect of total blindness before him, he sat a suffering spectator—

> "Unable to conceal his pain;
> And winked and looked, and winked and looked,
> Winked and looked, and winked again."

We read that the celebrated RAMSDEN used to present spectacles, fitted with common glass, to customers difficult to please, informing them, in the blandest terms, that these were exactly what was best suited to their peculiar vision. An exclamation of delight invariably followed: "Aye, *these* will do! *These* are capital!" A pair of empty rims were sometimes tried, by the same astute artist, with equal success, which "by the force of imagination added lustre to the scene." It is a fact, as true now as it was in Dr. KITCHENER'S day, that many persons seem to regard the determination of a particular curvature and power of lens (best suited to themselves) as a matter of unimportant detail. A pair of family spectacles, a century ago, whoever they may have suited originally, must, in the opinion of such persons have special virtues, for why should not family spectacles, like family Bibles, be equally useful at all times and unto all men? Not thus, however, can the mole-like individual be made to enjoy the visual range of the eagle. We read that the Earl of BATH assured Lord

Chesterfield, who suffered from deafness, that he would be happy to lend him an ear! "With truth more consoling than wit," wrote the *Quarterly Reviewer*, "may it be said to the thousands whose sight is defective, that the inventor of spectacles has lent them an eye. He has added to the pleasures and independence of age; he has lengthened life in protracting its usefulness; he has combined to wisdom the treasures of knowledge; he has preserved to the public the riches of wisdom; and for all degrees of men he has, times without number, kept the curtain from falling till the play has come to an end."

The above remarks have a close bearing on a tiny pamphlet, now lying before us, entitled—"Spectacle Missions: their Object, Advantages, Management, etc.," by Dr. Edward J. Waring, C.I.E., Fellow of the Royal College of Physicians, late H.M.'s Indian Medical Service. London: Kirby & Co., publishers, 440, Oxford-street, W. This little publication is one of a most pleasing character, affording, as it does, evidence of well-judged and sound philanthropy. The writer, a veteran in the ranks of science, and widely known by his valuable works on "Medical Botany" and "Materia Medica," here states, with touching simplicity, that when, owing to failure of his own health, and notably of failing eyesight, he was prevented from taking an active part in the work of life, he conceived the idea of organising a plan for the distribution of spectacles, and of extending its operations among the outside poor generally. The object of a "Spectacle Mission" is "the gratuitous supply of spectacles to those of the poor and hard-working classes who stand in need of them, and whose circumstances do not admit of their purchasing them." It has reference particularly to such persons as printers, seamstresses, tailors, shoemakers, and the like, who suffer from failing sight. It is meant to assist deserving persons whose livelihood depends upon unimpaired vision. Dr. Waring, after dwelling on the objects and advantages of the charity he is interested in, shows how such a mission is to be organised and conducted, and how with simple precautions it is not open to much abuse. It is in no way meant to encroach on the province of the ophthalmic surgeon; indeed, "it overlaps no other charity." The term *Spectacle Mission* is employed because an essential part of the charity consists in distributing, with each pair of spectacles, a copy of the Pocket Testament, or of the Psalms, published at the price of *one penny each*, by the British and Foreign Bible Society. All the details of the scheme are carefully laid down, and the important fact is made clear that, with a little trouble and care, a spectacle mission is really simple in its working, and not very expensive. £15 is estimated as covering the cost of 240 pairs of spectacles (each in a case), 240 New Testaments, and all probable contingent expenses. But a beginning can of course be made on a much smaller scale than this. No special scientific knowledge or qualifications are necessary to enable any kindly disposed person to work the scheme. The simple rules which are laid down in Dr. Waring's pamphlet, if carefully acted up to, are sufficient in themselves to ensure perfect success, and to teach any person of moderate means how, safely and efficiently, to accomplish a work of great utility. The poor and ignorant evidently stand in much need of a little sound advice on the subject of selecting or securing spectacles, as is proved by certain facts which Dr. Waring adduces; and which, sad from one point of view, are certainly somewhat quaint and humorous from another. Thus we are told that some persons have paid dearly, at second-hand shops, for glasses quite unsuited to their powers of vision, yet too valuable not to be worn. Others have been disappointed because "their missuses" do not suit them; while one poor man is known to have struggled to see clearly with "specs" inherited from his grandfather!

Dr. Waring has not only brought his scheme to bear on the relief of the inmates of different workhouses and asylums, but he has been able to establish and to keep going a spectacle mission at his own private residence, the influence of which now extends to four or five contiguous parishes, and the results of which have been highly satisfactory. His one thought, in publishing his present pamphlet, is to draw the attention of others to the nature of his useful mission, and to extend its scope in all directions, over the length and breadth of the land. No scheme more simple or more benevolent could well be conceived. We therefore heartily commend it to all persons, male or female, of charitable disposition, who are desirous of benefiting their fellow-creatures. We feel strongly that so excellent a charity ought to be made as widely known as possible. "All information," we are told, "as to its details will be gladly furnished in reply to an application to Miss C. Waring, Hon. Sec., Maida Vale Spectacle Mission, 49, Clifton Gardens, London, W." We have ourselves had an opportunity of carefully examining and testing the spectacles distributed by Dr. Waring, and, what is better still, we have the authority of a most distinguished expert for saying that, in spite of their wonderfully low cost (one shilling a pair, in a case), they are well made, and very efficient. Unlike Dr. Kitchener, sixty years ago, Dr. Waring will be delighted if all who read his little pamphlet will let their friends and acquaintances also read it. Fortunately, too, opticians of the present day do not object to the public being enlightened on such matters. Like William Cooper, in 1847, Dr. Waring has thought more of the public than himself, and he certainly has not devoted a syllable to the display of his learning at the expense of his judgment. With such glasses as Dr. Waring distributes gratuitously, Pepys might have gazed comfortably on "the light which hurt his sight;" and with them it is certain that Dr. Waring is daily making the poor happy, and, to the great joy of many, keeping the curtain from falling until the drama comes to its legitimate end. We have read of Heberden writing his wonderful "Commentaries," when he had reached fourscore years, and of his remaining cheerful till the age of ninety-one, although years before his death he met with

an accident which disabled him for ever afterwards. We also recall the case of the great MORGAGNI toiling at professional subjects till his eightieth year, and completing his greatest work ("De Sedibus et Causis Morborum") after blindness had seized him, being assisted in his labours by the then youthful and afterwards renowned SCARPA, who, when their daily task was completed, was wont to amuse old MORGAGNI by reading to him his favourite classics. Such are the men of whom it may truly be said that they were "great in goodness as in wisdom." Not less pleasing and touching, it appears to us, are Dr. WARING'S noble efforts, with his daughter's gentle, kind and intelligent assistance, to relieve affliction, such as he himself has had personal knowledge of. Thinking of such high-souled benevolence, and of the loving spirit in which it is carried out, we can only say, O! SANCTA SIMPLICITAS. May Spectacle Missions soon come to be much more numerous and widely known than they are at present.

THE late meeting of the Medical Council was in many respects a memorable one. For the first time it put in force the penal clauses which it has the power to enforce against conduct infamous in a professional respect. Two practitioners were accused of covering. The first charge was against Dr. ALEXANDER LINDSAY, that he, being a registered medical practitioner, had acted, and did still act, as cover to one EDWIN MIDDLEBROOKE, of Smallthorne, Stoke-on-Trent, in the county of Stafford, an unqualified person, thereby enabling the said EDWIN MIDDLEBROOKE to carry on a medical practice as though he were a legal medical practitioner. This charge was fully inquired into, and substantiated, and the Council moved "That the Registrar be directed to remove the name of Dr. LINDSAY from the 'Medical Register.'" A second charge was formulated in somewhat similar terms against a Mr. S. J. DALY, a Member of the Royal College of Surgeons of London, for covering a Mr. BILLING, of Blackpool. This charge, on investigation, was proved to be true, and a similar penalty was inflicted upon Mr. DALY. Two other accusations were made against two other medical practitioners for covering, but both were dismissed by the Council. The action of the Council has been marked all through with absolute fairness, and the Council is to be congratulated in thus vindicating its position as the arbitrator in matters which are of the deepest importance to the profession. The punishment inflicted is severe; but as the object of law is not only to punish, but to deter, it is to be hoped that after a time, when the offence has been purged, the Council may take into their consideration the propriety of restoring their names to the Register.

Covering is very extensively practised, and these cases should serve as a warning to those who are now implicated. It is a popular opinion that the enforcement of law is always expensive. This has been again illustrated in connection with these cases, the sum of £800 being expended on the Council, owing to the length of the investigation. This is an enormous waste of money, and the Council have very wisely referred all future investigations to a committee. Had the two other charges been gone into, it would have involved another sacrifice of £800. The employment of unqualified assistants is on the decline, though there is still a large number engaged. Practitioners must remember that they are running a great risk, and that they may at any moment be brought up before the Council on the charge of delegating their duties to unqualified practitioners. We have previously expressed our opinion on the subject of unqualified assistants. We are of opinion that some *via media* should be established in regard to them. There are a number of men in their ranks who have acted as assistants for years, and it would be positive cruelty to turn them out on the world without a means of livelihood. The profession has nourished and encouraged these men, and the profession itself is to blame for the fact that we have unqualified assistants at all. Now in the *via media*, provision should be made for these gentlemen. We do not desire to sketch out a perfect scheme, but we may suggest the lines on which such an one should be drawn. There should be a proviso that unqualified assistants shall not any longer be tolerated (this is to prevent any addition to the ranks), save with the following exceptions:

(*a*) All unqualified assistants at present *bona fide* employed may continue to act under certain conditions.

(*b*) That the names of all unqualified assistants *bona fide* employed should be registered and published in a special book like the "Dentists' Register."

(*c*) That all registered should specify to the registrar whether they had attended any course of lectures on hospital practice, or how they had obtained entrance to the profession.

(*d*) That a certain number of certificates should accompany applications, such certificates to be signed by those who had employed the assistants, and certainly testifying to the character of the applicant.

In process of time all these registered assistants would die out, as no addition would be allowed to this Register. There would probably be a couple of thousand names sent in, and the registrar would have additional work on his shoulders for a short time, but we believe that in the end it would save him a large amount of trouble and correspondence. Many objections may be taken to such a scheme, and it is no doubt imperfect. We submit it for criticism, and hope it may receive the attention of some of our representatives on the Medical Council. Extreme men will say that we should not in any way countenance unqualified assistants, and we should drive them out of the profession at once. We answer, this would not be justice. The Council are fully alive to the importance of exercising disciplinary powers: we find appended to the minutes of the General Medical Council, November and December, 1888, a number of documents relating to the question from qualifying bodies. We know from the past that the colleges and the universities will not move in matters affecting their

licentiates or graduates, and it would be a retrogression to take away from the Council its disciplinary powers, and vest them in the qualified bodies themselves—in other words, that the qualifying bodies should first investigate the charge, remove, suspend, or censure, and that the Council should then give effect to the decision by ordering the erasure of the name from the Register. We trust that the Council will strongly resist any proposal of this nature.

The Council had to spend some days in considering the reports of the visitors to the examinations. It would appear that the Glasgow and Irish examinations, by insisting upon operative skill on the dead body as a test for examinations, are in advance of the other examinations. The following motion, passed by the Council, will no doubt stir up the English examining bodies to make their examinations on a level with the Glasgow and Irish examinations:

"That the Council, being of opinion that the performance of operations on the dead body is a highly important part of a complete test for the efficient practice of surgery, regrets that so many of the licensing bodies in England and Scotland have not hitherto felt themselves able to render their examinations complete in this respect; and the Council —while prepared to admit the existence of difficulties connected with the anatomical supply—earnestly recommends to those bodies to reconsider the means they might use for amending that part of their examination."

There has been a new issue of the Pharmacopœia. This sitting of the Council has not been an unprofitable one, and it certainly has moved in a direction which the profession has long desired it to take. If there be any desire on the part of the Council to rid itself of its disciplinary powers, we trust the profession at large will protest against such a proposal.

AT a recent meeting of the New York Academy of Medicine Dr. BOWDITCH, of Boston, read a paper on the subject of "Tolerance and Intolerance in Medicine," in which he strives to put back the hands of the clock. A certain section of the profession in America are anxious to do away with all codes, except the one of doing unto others as you would have them do to you—a code which, unfortunately, leaves too much to the individual and to his interpretation of this golden rule. The British Medical Association, the largest medical organization in the world, has, after repeated discussions, and after soliciting the opinion of its members by means of its branches, decided that homœopaths should be excluded from membership. This intolerance in an old country, where the profession is both in a higher state and better in hand than it is in America, should be taken into consideration by the New York Academy of Medicine before they accept Dr. BOWDITCH'S advice. In America, besides homœopaths, there is a large number of irregulars, and as far as we can gather from our American cotemporaries the profession is suffering from the competition of this irregular class of practice. On the other hand, the profession is striving to elevate itself by insisting on preliminary examinations, a graded course of not less than three years, with compulsory attendance on lectures, etc. Protests are made against the multiplication of schools. Schools which have not proper teaching facilities have been denounced by the press of America. Still more, in all the large American centres of education admirable post-graduate courses have been arranged to complete the education of those who have graduated, and to give another year of study. It is to the credit of the American Medical Association that they have adapted a high-toned code of ethics, and that it compels all affiliated societies to accept this code; and it is still more to the credit of American physicians that the majority of the State associations have cheerfully accepted the ethical rules laid down by the parent society. The New York State Society rebelled, and it met with the fate it justly deserved—it was expelled. Codes of ethics are at times very disagreeable. When a surgeon or physician has a consulting practice in such a centre say as New York, which abounds with irregulars, it requires a certain amount of abnegation to refuse to meet a homœopath, or eclectic; it means the sacrifice of so many dollars, or hundreds of dollars, and very often the irregular is the best client of the consultant. The code of ethics of the American Medical Association, just like our English code, has been framed in the best interest of the public as well as of the profession. In England homœopathy has been examined by such men as Dr. LAUDER BRUNTON, RINGER, etc., and its tenets have been pronounced unscientific. It has been rejected in France, Germany, and Austria, even though some of its professors are men of high integrity and intelligence. The cause is finished. We object to specific names being given to ourselves. We decline to be called allopaths, and we cannot countenance any body of men who give themselves distinctive names. The homœopaths have cut themselves off from the regular profession by their own choice. In England they have not increased in numbers, through our bigotry, nor has the profession lost caste, because, after calmly discussing their principles, we have rejected them. At the same meeting at which Dr. BOWDITCH read his paper, Dr. MCINTYRE also read a paper, entitled "Which is the Liberal School?" In the course of his paper he says, "These gentlemen built a wall round themselves, separating them from the general republic of medicine. This is the exact position, and the solution of the difficulty does not rest with us, but with those who have, of their own free will, adopted a name and title which has been but too often a cloak of ignorance and a trade-mark." The American Academy of Medicine deservedly occupies a high place in medicine. Its fellows are distinguished and known beyond their own country, so that whatever action they may take in this matter will be submitted to the criticism of the profession, not alone of America, but of the world. Dr. BOWDITCH says in his paper that "the Academy will not recover its just position until it rescinds the vote adopting the American code of ethics." In view of the action of the British Medical Association, we trust that the Academy will not hesitate in its answer in the negative. The golden rule of

life would no doubt be better than any code, but, unfortunately, we have found out in the process of civil government we cannot depend upon the acceptance by each individual of this high code. Even in New York we found the policemen patrolling the streets, and we believe that America has a penal code for those who transgress her laws. The American code of medical ethics is not a selfish one; it is not illiberal; it is not even framed for the protection of the profession—it is the public who gain by it. It may press, and does press rather hardly, on the very liberal-minded surgeon or physician who is willing to meet anyone for a consideration, but it does not press on the honourable or the high-minded, who have faith in medicine and medical teaching, and who will not sanction the various forms of charlatanism by which the public are deceived and cheated.

Annotations.

"Forsan et hæc olim meminisse juvabit."

CHRONIC LEAD POISONING.

We publish in our correspondence columns an admirable letter on the subject of lead poisoning—a personal experience of the writer, hence all the more valuable. The description given of the initial symptoms and progress of plumbism will put practitioners on the alert, especially when there is any doubt as to diagnosis.

THE BLACKPOOL PUBLIC AND THE MEDICAL COUNCIL.

The action of the Medical Council in ordering the erasure of the name of the practitioner who covered Mr. Billing has excited the indignation of a portion of the Blackpool public, and indignation meetings have been held to protest against the punishment inflicted by the Council. A clergyman presided at one of the meetings, and delivered a violent harangue, chiefly remarkable for its bad taste. It is very singular that amongst the clergy we find such strong supporters of unlicensed practitioners; but as we have often remarked before, education does not afford any protection against quackery. The Blackpool meeting is not deserving of notice, save as an illustration of mental blindness.

THE EDINBURGH SCANDALS.

We have received marked copies of the *Scotsman* and the *Scottish Leader* containing very strong articles on the recent decision of the University authorities on the matter in dispute between the professor of physiology and his late assistant. It is alleged that Professor Rutherford has been whitewashed, and that great dissatisfaction is felt at the manner in which the enquiry was held. It is impossible for us to pronounce an opinion, as we have not been able to read the evidence, as the enquiry was held in camera. It is probable that we shall hear more of the case this time in the Law Courts.

POST-GRADUATE SCHOOLS.

For some years post-graduate schools have existed in the United States, the one at New York being, we believe, the earliest, as it is now the most influential in America. The great success attending the American post-graduate courses has led to their introduction into England, and we are pleased to hear that a scheme is on foot to establish in London a Post-Graduate Polyclinic after the model of the New York one. We feel sure that young men just qualified will appreciate a course of lectures on special subjects which will equip them all the better for their life's-work, if the fee be kept within a moderate limit. It should be remembered that after qualification-fees, and after the expenditure during student life, funds have to be husbanded so that the question of the honorarium for the course is a very important one. The clinical material available in London is greater than that of any capital in the world.

MEDICAL PROVIDENCE.

We feel a pleasure in being able to still chronicle the financial success of the Medical Sickness and Life Assurance Society. We put the following facts before the profession and before its junior members. Upwards of £6,000 has been disbursed for sick pay, and £1,150 for death during the short time it has been in existence. As to security we can point out—that the Society has to its credit a capital of £28,000, invested in the soundest securities, and an increasing annual income from premiums. Accidents are included under the term "Sickness," and the liability to accidents, especially in the country, is well known. The Society owes its present position to the economical and efficient management of a few devoted medical men, who advance its interests. Junior practitioners should write for prospectuses to Mr. J. C. Radley, 26, Wynn-road, Brixton, London, S.W.

BRITISH MEDICAL ASSOCIATION.
LEEDS MEETING, 1889.

The programme of the Leeds meeting, 1889, is already issued. Judging by it, it promises to rival any former meetings. Leeds has a reputation to maintain, and it is evidently intending to keep up its prestige. The Association will meet on the 30th of July and following days, Mr. Wheelhouse being the President-elect. Dr. Hughlings Jackson will deliver the address in Medicine, and Mr. Teale that in Surgery, while a new element will be introduced into the public addresses by an oration on Psychology by Sir Crichton Browne. The Presidents of Sections will be: In Medicine, Dr. Clifford Allbutt; in Surgery, Mr. Jessop; in Obstetrics and Gynæcology, Mr. Cullingworth; in Public Medicine, Mr. Edison; in Psychology, Dr. Hack Tuke; in Pathology, Dr. Joseph Coats; in Ophthalmology, Mr. Anderson Critchett; in Diseases of Children, Dr. Scattergood; in Laryngology, Mr. Butlin; and in Otology, Mr. Field.

THE DRESS OF WOMEN.

It is an old saying, "when doctors disagree, who shall decide?" This is again illustrated by the discussion which is taking place on the value of the corset, and on braces *versus* the suspension of garments from the hips. It has lately been alleged that corsets are not injurious, and that they are admirably adapted for the purposes for which women now put them. Braces for suspending under garments have been recommended, so as to throw the weight off the pelvis. In the new form of dress this method is adopted, and *prima facie* it would appear to suggest advantages over the old method, but even this inovation will not be tolerated. The old system is held to be far superior in every way. Dress reform, we fear, is in the remote distance.

ELECTROLYSIS.

We recently published an account of Dr. Keye's experiments "On the Treatment of Urethral Stricture by Electrolysis," which were unfavourable to the methods at all points. We prognosticated that Dr. Newman would hardly be content to allow Dr. Key's observations to pass without protest, and we publish a reply which has been kindly forwarded to us by Dr. Steavenson. The accumulative evidence in favour of Dr. Newman's plan cannot be disposed of by the simple *ipse dixit* of any individual surgeon however eminent, and we therefore commend to our reader's attention Dr. Dickson's paper.

THE SACCHARINE CONTROVERSY.

A controversy has recently taken place between Dr. Pavy and M. Worms on the therapeutic action of saccharine, and Dr. Fahlberg has had to write to the journals in defence of his offspring. The Pavy-Worms controversy arose out of a mistake. Nothing can be gained in discussing a matter of this kind by imputing disinterested motives to those who condemn or use saccharine. It has been alleged that the objection to this agent in France arose from a desire to protect native industries—a conclusion hardly warranted by the facts. Mr. Worms, in his reply to Dr. Pavy, very justly emphasises this aspect of the question, and says: "M. Pavy et le rédacteur de la *Lancet* avec lui suspectent l'existence en France de *quelque motif puissant* pour déprécier ce qu'ils apellent la grande acquisition. Je ne me permettrai pas de supposer qu'il existe à l'étranger quelque motif puissant pour en dissimuler les inconvénients."

MEDICAL CLUBS.

At first sight it would appear that medical social clubs were very excellent institutions, that it was a good thing to bring members of the profession together, and out of such a numerous profession we ought to be able to support a club. Men with a partiality for club life actually prefer clubs in which the medical element is absent. The reason for this is not far to seek. Practitioners who seek relaxation at clubs desire to escape from professional associations, to thoroughly unbend their minds, and there is something in the atmosphere of a pure medical club redolent of what is technically known as "shop," for medical men, however social they may be, have a distinctive tendency to revert to medical topics, and to converse on what is uppermost in their minds. We regret to hear of the demise of the Galen Club.

EDGED TOOLS.

We published in the December number an account of Ortel's method of cure for certain heart affections. The fundamental principle appears to be that disturbed compensation is to be restored by exercising the heart. This is achieved by walking up hills, the walks being duly graduated and progressive. In suitable cases this system has no doubt been successful, but here comes the difficulty—which are the suitable cases? We all know that fatal results have followed from over exertion of a trifling character in cases of failing compensation, so that it appears to us that we are playing with edged tools in adopting the principle of exertion as the cure for failing heart. A note of warning has been struck in Germany by Leyden and other authorities, and it is reported by Scholl that harm has been done to patients who have been treated by Ortel himself. Each case of heart failure has of cause to be judged on its own merits.

WHAT IS PISTOIA POWDER?

In an article in the *L'Union Médicale*, December 11th, 1888, this question is put to the pharmacists. Pistoia is a town in Tuscany, at the foot of the Apennines, where there exists a religious community who prepare a powder possessing alleged sovereign virtues. The powder is of a green colour, and tastes slightly warm, leaving a bitter flavour in the mouth. The writer desires to know whether it is made of gentian, with some alkaline salt, etc. It is only sold by the kilo, divided into 365 packets; one to be taken every morning fasting in a large glass of water. Large quantities are sold and taken by persons who suffer from rheumatism. M. L—— in the *L'Union Médicale* says, in explanation of the reason why he desires to know the composition of the powder: "The public is unfortunately disposed to believe that medical men despise all medicines which are not first produced with the official stamp. This belief is false. Medical men have no other pre-occupation or interest but to cure, and they would be foolish not to accept measures for that end, no matter from whence they come. I say to the pharmacist, here is a powder at present mysterious, surprising effects of which, rightly or wrongly, are related, and the success of which appears to increase in proportion to the silence of the academy." Perhaps some English chemist could answer the question?

CAVEAT EMPTOR

Who is really responsible for adulterations—the seller or the buyer? we are inclined to blame the buyer. There is a fair market price for most articles, and in the instance of drugs

this is well known. If you want a good article you will have to pay a fair price, but if you insist upon obtaining something at a low figure which in the market is marked a high one, you must expect to be cheated. The seller cannot afford to give anything away, but he meets the difficulty by sophistication or adulteration. Cheapness has been pushed to such an extreme that you can have a suit of clothes for 8/6; who could expect wool *at that* price. The same is true of pharmaceutical preparations. The buyer is very largely responsible for the cutting down the prices, and for the evils of sweating. Supply is controlled by demand, so that in the case of adulteration it is the buyer who is very much to blame.

New Remedies.

Carbonaphtholic acid.—This new antiseptic is obtained by the action of carbonic acid on naphthol in the presence of sodium. It possesses powerful antiseptic properties, but in large doses it has proved poisonous to animals, and therefore requires to be used with caution. It is almost insoluble in water, but is sparingly soluble in a solution of borax and sodium phosphate, and also in ether and alcohol. A solution of one in 20,000 is said to kill putrefactive organisms, and one in 300 to stop decomposition, even when it is administered in an advanced stage.

The *Aluminium sulphites* are stated by Dr. Wade, in a paper lately read before the Michigan State Medical Association, to be valuable antiseptics, since they are non-poisonous and non-irritating. In cases where a soluble antiseptic is required, the persulphite is suitable, and the sesquisulphite, which is insoluble in water, is available in cases where an external insoluble application is desirable. Dr. Wade states that as much as thirty grains of the sesquisulphite have been taken internally without causing discomfort. He assumes that the germicidal power of these sulphites is not less than that of acetate of aluminium—viz., one to 6,310, and is therefore only about half the strength of that of bichloride of mercury. The sesquisulphite is prepared by mixing aqueous solutions of ten parts of potash alum and eight parts of sodium sulphite, and carefully washing and drying the precipitate. The persulphite is made by dissolving the freshly precipitated sesquisulphite in sulphurous acid and crystallising without heat.

Salicyl and *Thymol mercury* have been employed with good results in the treatment of syphilis. A 10 per cent. suspension of the remedy in liquid paraffin was used. Six or eight injections are said to cause the disappearance of the symptoms in a rapid and energetic manner. It is said to be nearly equal in this respect to a 10 per cent. "calomel oil," and to be far superior to "gray oil."

Pyrodin is the latest antipyretic, and is said to consist of acetylphenylhydrazine, or some nearly allied substance. Dr. Dreschfeld, of Manchester, has experimented with it on patients suffering from various fevers, and has published his results in the November number of the *Medical Chronicle*. He finds that it is a powerful antipyretic, reducing the fever temperature rapidly, and keeping it at a low level for several hours, producing at the same time marked diaphoresis, without either nausea, vomiting, or collapse. It appears to be specially applicable in cases of pneumonia, typhus, or scarlet fever. But it is not advisable to give repeated doses at short intervals, since then the drug acts toxically on the blood, and produces hæmoglobinæmia. Once in eighteen or twenty-six hours is often enough, unless the temperature is very high, and its use should not be continued for more than a few days. The dose for children is three or four grains, and for adults eight to twelve grains. It is considered by the author to be more powerful than either antipyrin, antifebrin, or phenacetin. It is a white crystalline powder, only sparingly soluble in cold water.

Benzanilid and *Salicyl anilide* are, with acetanilid (antifebrin), the only members of a series of anilides experimented with by Dr. Kahn, which have given good results as antipyretics. Benzanilid is claimed to possess the advantage over antifebrin that there is an absence of subsidiary action following its use. It is prepared by boiling together benzoic acid and aniline in equivalent proportions, or by the action of benzoyl chloride on aniline. It is a white crystalline powder, soluble in fifty-eight parts of alcohol at 20° C., or seven parts of boiling alcohol, but is difficultly soluble in ether. The dose for children is 0.1 to 0.6 gram.

Cerium oxalate is now recommended by Dr. Cheesman, of New York, as a valuable remedy for cough, especially for the earlier irritant cough of phthisis, for chronic bronchitis, and for spasmodic asthma, whooping cough, and measles. The dose is five grains, given early in the morning or at bedtime, and increased to ten grains or more. It should be given on an empty stomach in fairly large doses, rather than in frequent smaller doses. It is most advantageously used in the dry state. Doses of twenty grains, several times a day, have not produced any dangerous symptoms.

Saccharin has been the subject of a series of experiments by Drs. T. Stephenson and Woolridge, with the view to ascertain whether saccharin interferes with the digestive powers, as asserted. They find that it is quite innocuous when given in quantities even largely exceeding the amount that would be taken in ordinary diet; that it does not interfere with the processes of digestion when used in any practicable quantity; and that it may be administered for a considerable period without injuring the bodily functions.

Imperialine is the name of a new alkaloid recently obtained by Herr Fragner from the crown-imperial (*Fritillaria meleagris*), which yields it to the extent only of 0.08 to 0.12 per cent. It crystallizes in short needles, and although very slightly soluble in water, it yields a crystalline hydrochlorate, which is readily soluble in water and alcohol. Its formula is $C_{35}\ H_{60}\ N\ O_4$. It is said to possess a physiological action on the heart.

Dioscoea villora has been examined by M. Kalteyer, the active principle being hitherto unknown. It is found by M. Kalteyer to contain a substance allied to saponin in considerable quantity. A resinous principle obtained from the root, and known as dioscorein, is used by American eclectics in the treatment of colic.

Yeast has long been known to be of value when applied externally in the form of a poultice to gangrenous ulcers, etc.; but the value of its internal administration appears to have been recognised only by a few, since Dr. Heer has thought it advisable to publish the results obtained by him in the treatment of some contagious diseases. He says that bottom yeast acts as a remedy for diphtheria with a rapidity unequalled by no other. In scarlet fever, dysentery, and infantile diarrhœa, he has used it with favourable results. To this list may be added, from the experience of the writer, that it is very valuable in rapidly healing up the abscesses left sometimes after an attack of small-pox, when taken in doses of a teaspoonful in warm water with sugar three times a day. Dr. Heer recommends it in doses of one to three grains every two hours for children up to three years old, six to eight grains for older children, and ten to fifteen grains for adults.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

Antiseptic Treatment of Abscesses. By Dr. Lucas Championnière (*Journal de Médecine de Paris*, November 18th, 1888).—Before opening the abscess, the cutaneous surface is to be washed with a solution of phenic acid; the bistoury that is used is to be immersed in phenic acid water, and the cavity to be injected with the same fluid. A drainage tube should be inserted, and covered with a thick layer of charpie impregnated with a solution of phenic acid and glycerine. The tube is to be removed, for the purpose of washing, at the end of twenty-four hours, and again covered with charpie. The whole to be covered with gummed oil-silk. Suppuration is lessened, and the cicatrix smaller under this plan, which is suitable in every respect for mammary abscess.

Hysteria from Poisonous Influence of Sulphuret of Carbon (*L'Union Médicale*, November 18th, 1888).—At the meeting of the Société Médicale des Hopitaux, November 9th, M. Marie reported two cases of hysterical hemiplegia in workers with sulphuret of carbon, in whom there existed hemianæsthesia with contraction of the field of vision and marked disturbance of the general and special sensibility. The zones of anæsthesia were not distributed according to the course of the nerves, but limited to a circular line passing through the proximal extremity of the limb. Motor trouble affecting the muscles of a portion or the whole of a limb. Not frequently convulsions occurred. There was constant headache and night-mare, emotional excess, and melancholy. In some instances the symptoms occurred suddenly, assuming an apoplectic form.

A Substitute for Tracheotomy and Intubation. By Dr. Edgar Holden, of Newark, New Jersey (*South-Western Medical Gazette*, Louisville, Ky., October, 1888).—Under this heading Dr. Holden read an excellent paper descriptive of a new and safe method of overcoming laryngeal obstruction. A short description was first given of its numerous causes, and of the sudden emergencies that call for the utmost haste in giving free access of air to the lungs as the only means of saving life. A long list of recorded mistakes, accidents, and dangers attending intubation was accompanied by a somewhat similar record in the history of tracheotomy. The ingenious instrument he presented is obviously so designed as to render most of these unfortunate complications impossible, while operating with greater ease and rapidity. Thin silver blades were introduced through the crico-thyroid membrane and passed between the vocal cords. These are separated by pressing together the two short external extremities, which are at right angles to the rest of the blade and united to each other by a hinge where they rest in the wound. Pressing the other ends together separates the inner blades between the vocal cords. Advantages :—Easy of introduction and removal ; cannot be displaced ; breathing through natural passages ; no interference with swallowing, etc. Also well adapted for removal of foreign bodies in the trachea. A drawing was next shown of a very long silver tracheotomy tube, designed by A. Gouguenheim, of France, the lower end having flexible spiral. Introduction easier, and injurious pressure avoided.

Sulphate of Physostigmina in Chorea (*Journal de Médecine de Paris*, November 18th, 1888).—M. Riess has recommended the hypodermic injection of physostigmina in chorea twice a day, in doses of a milligramme. He has seen the symptoms cease in five or six days. The influence is not so good in chronic cases. M. Riess has found satisfactory results from this treatment in tetanus, paralysis agitans, sclerosis of the medulla, and augmentation of reflex movements.

On the Anatomical Elements of Milk, and the Organisation of the Globules. By M. Bechamp (*Union Médicale*, November 20th, 1888).—M. Bechamp remarks that, contrary to former opinion, which he holds to be erroneous, it may be shown that milk is not an emulsion, that its globules are not simply fatty matter, but anatomical elements formed in the gland at the same time as the complex fluid in which they float, like the blood globules and leucocytes in liquor sanguinis ; that, in short, as stated by Dumas, they are vesicles or cells, furnished with envelopes. M. Bechamp further shows that milk contains, besides caseine, other coagulable substances, and that it curdles and ferments spontaneously without the aid of extraneous organic ferments. These globules may be isolated from cream or curds by mixture with diluted alcohol, and subsqeuent washing in a dilute alcoholic solution of sesquicarbonate of ammonia. The globules may be found intact in the field of a microscope.

Aggravated Hysteria : Favourable effects of Sulphur Baths. Dr. Schwarz, Baden bei Wien (*Centralblatt für Gynäkologie*, No. 46).—An anæmic patient, seven years of age, was suffering from functional derangement and psychical disturbance, with painfully tonic cramp in the extremities, so as almost to prevent locomotion. The cutaneous surface of the lower limbs was without sensibility as far as the middle of the thigh. The upper limbs were feeble, and so much affected with tremor as to prevent any manual work. The patient suffered also frequently from vertigo, faintings, and sleeplessness. The bowels acted only once in from eight to fourteen days. Menstruation had not occurred. After the use of five sulphur baths the catamenia appeared. After fifteen baths, the cramps of the lower extremities subsided ; after thirty-one baths, all other derangements disappeared.

Chresylic Acid—a new disinfectant By M. E. Gautrelet (*Journal de Médecine de Paris*, Nov. 25th, 1888).—This acid is the result of the action of caustic alkalies upon phenol, the action of which as a parasiticide is greatly augmented by the combination. The caustic properties, however, of the chresylic acid, M. Gautrelet adds, interferes with its general employment.

On the Treatment of Uterine Fibromata by Intra-uterine Electrolysis. By M. Delétang (*L'Union Médicale*, November 29th, 1888).—M. Delétang since 1884 has treated altogether 97 females, on the method of M. Apostoli. The immediate effects, as stated by M. Delétang, are : *a.* Contraction of the mass of the uterus and tumour. *b.* Congestion of all organs in the electric circuit ; this congestion, almost constant and persisting for hours, accompanied with colicky pains. *c.* Sudden suppression of pre-existing hæmorrhage. The secondary effects are the disappearance of hæmorrhage, and the amendment of functional derangement, together with the diminution of the morbid mass, and occasionally its total disappearance.

Case of Nephritis caused by a Cantharides Plaster. By Dr. Pennel (*Journal de Médecine de Paris*, November, 1888).—M. S—— æt. twenty-five years, contracted syphilis in April, 1888, and was immediately placed under mercurial and iodide treatment, which was continued till November. In June or July he had suffered from cough and night-sweats with pains beneath the clavicle, and some degree of emaciation. The syphilitic symptoms also became aggravated. In October a general improvement occurred. At the end of the month of November it was deemed advisable to supply a blister plaster. On December 5th, there was suddenly developed severe headache, with swelling of the features. General symptoms of nephritis continued until the end of January, when a sensible amendment took place. Albumen was present in the urine until the following April, when it disappeared ; the urine abundant and clear. Albumen had been present four and a half months. From this time convalescence was progressive. The interest in the above case was to be found in the suddenness and gravity of the symptoms, and Dr. Pennel observes, its correspondence with similar effects that he has witnessed from cantharides.

II.—NOTES FROM FRENCH JOURNALS.

By H. R. HATHERLY, M.R.C.S.

Congenital Fibro-myoma of the Tongue (*L'Union Médicale*).—Dr. Pancet has reported a case of congenital fibro-myoma of the tongue. The tumour had the appearance of a supernumerary tongue, and was about the size of a pigeon's egg. It was of rounded form, of yellowish colour, reddened in parts by the presence of small blood-vessels. The growth had become developed in the sub-mucous cellular tissue. It was adherent to the mucous membrane, and to the subjacent muscular tissue. The central portion consisted of one great fatty lobule, surrounded by fibrous tissue, yellowish, and rather hard. A histological examination proved the growth to be a fibro-lipoma.

Statistics of the Pasteur Institute (*Bulletin Médicale*).—During the month of September 121 persons were treated in the Pasteur Institute, of whom sixteen were bitten by animals whose madness was established by experiments ; seventy-five were bitten by animals recognised as being mad, after a veterinary examination ; and thirty were bitten by animals suspected of madness. There was one death—Jean Couzinier, æt. sixty-five, who was attacked by hydrophobia three days after the completion of treatment.

Infection of Tetanus (*L'Union Médicale*).—The discussion of Mr. Terrillon's paper, before the Chirurgical Society, has elicited from several members facts which seem to bear out the theory that cephalic tetanus is an infectious disease. The discussion is probably but a prelude to that which will take place at the Academy of Sciences and Medicine, when Dr. Verneuil brings up his report on the researches of MM. Berger and Richelot.

Total *versus* Partial Hysterectomy.—This is the subject for discussion at the next meeting of the Chirurgical Society.

Vulvo-vaginitis in Children (*L'Union Médicale*).—Dr. Ollivier looks upon vulvo-vaginitis as a contagious disease. Two children suffering from this affection were admitted under his care, and were, then, the only cases. Three weeks afterwards fifteen other children were successively attacked by the same disease. An enquiry into the causes of this outbreak elicited the following facts from the nurses :—The same sponge was used for all these children ; the nurses did not wash their hands ; the children used the same chamber vessels and closets, and the closets were not properly cleansed. No case of the disease occurred after Dr. Ollivier had adopted measures of strict cleanliness and disinfection. Dr. Ollivier and his assistants are endeavouring to discover a microbe, and its mode of transmission, by experimental methods.

Gift to the Association of French Medical Men (*L'Union Médicale*).—Dr. E. Belle, of Moissac, Tarn et Garonne, who died last September, has bequeathed to the Association the whole of his fortune, amounting to more than 100,000 francs. He directs that grants of 500 francs are to be made to medical men who have been unfortunate.

Hæmorrhage after Tooth Extraction (*L'Art Dentaire*).—M. Fouquet points out a very simple method of arresting the troublesome hæmorrhage which occasionally follows tooth extraction. He cuts a piece of cork in the form of a plug, to fill, as accurately as possible, the alveolus, the top part being left large enough to slightly overlap the gum. The closing of the jaws suffices to compress this improvised plug at will, and in a short time all hæmorrhage ceases.

Pyridine as a Cardiac Stimulant (*Journal des Sciences Médicales de Lille*).—Dr. De Renzi has found in pyridine a good cardiac stimulant. His conclusions are based on the action of this remedy in seven cases. He asserts (1) that pyridine given internally in daily doses of from six to ten drops in water, is well borne, and the dose may be gradually increased to twenty-five drops, and even more. (2) The remedy increases to a remarkable degree the cardiac systole, and diminishes the sense of oppression and anxiety. (3) The number of pulsations and respirations is lessened. (4) Arterial blood-pressure is increased. (5) Sphygmographic tracings indicate that the line of the ascending curve is raised, at the same time pulsation being more even; in one clearly arhythmic case the rhythm was entirely regained, and the pulse became perfectly regular and normal. (6) Pyridine has also cured angina pectoris, and has relieved the attack more rapidly and certainly than any other remedy.

Dislocation of the Coccyx of Long Standing (*L'Union Médicale*).—A case has been reported by Dr. Hue, in which the coccyx had remained dislocated for three years. The sitting posture was always painful, and a frequent change of attitude was needful. On making a rectal examination, Dr. Hue could easily diagnose a forward displacement of the bone projecting from the curve of the sacrum. The reduction was almost effected by the mere examination, and was accompanied by sharp pain and a desire to vomit. The patient was at once relieved of all distressing symptoms, there being only a dull sense of weight for a few days.

Large Ovarian Cyst (*L'Union Médicale*).—Dr. Petel exhibited, before the Medical Society of Rouen, an ovarian cyst of unusual dimensions. The circumference was one metre, and it weighed 15 kilogrammes, 300 grammes. The incision necessary for its extraction measured, eight days after the operation, thirty-seven centimetres.

Apostoli's Treatment (*L'Union Médicale*).—A new method of applying the galvanic current has been introduced by Apostoli, who applies an intra-uterine chemical galvano-caustic, which may be either positive or negative, according to the case. He has a double object: First to treat the mucous membrane of the endometrium, which is always unhealthy; and secondly, to utilise the interpolar trophic action to attack at the same time lesions of the parenchyma, which nearly always co-exist. He obtains an anatomical wasting, varying from a third to a fifth (but never the entire diminution of substance) a rapid and lasting cessation of hæmorrhage, a disappearance of the phenomena of compression, and general symptomatic relief.

Treatment of Intra-cranial Abscess following Disease of the Ear (*L'Union Médicale*).—Dr. Chauvel read a paper on this subject before the Academy of Medicine. A few years ago, if intra-cranial abscess was suspected, it was usual to advise non-intervention. In the present day, discoveries of the functions of the brain, and the impunity of operations which expose its substance, have rendered such a doctrine untenable. He relies upon the facts already published by several surgeons, and on two cases observed at Val de Grace, which had a fatal termination, as material for the following conclusions:—1. Intra-cranial abscesses which are consequent on lesions of the ear do not possess any definite symptomatology, so that they are difficult to diagnose with certainty. When there are reasons to suspect them, intervention is necessary, antisepticism rendering the operation itself but slightly dangerous; if there should be but one patient in ten cured, it would justify the operation. 2. These abscesses are generally situated in the temporo sphenoidal lobe. 3. When the direct treatment of otitis has been exhausted, and cerebral symptoms are evident, the mastoid apophysis must be trephined and a few days be allowed to pass, when if no improvement follow the skull must be opened. 4. The guiding points are: a horizontal line passing from the external commissure of the eyelid, two vertical lines passing one before and one behind the pavilion of the ear. The point to trephine is on the horizontal line, at an equal distance from the two vertical lines, and this point should correspond with the squamous portion of the temporal bone; the only blood vessels which can be met with are branches of the middle meningeal artery. 5. The cranium being opened, if there is an abscess a prominent and more resisting point will be found. It will be opened according to rule. Numerous failures may be expected, either from the trephining not having been made at the level of the abscess, or from the abscess being multiple.

Dilatation of the Uterus (*L'Union Médicale*).—Dr. de Saint Moulin, referring to recent advances in gynæcology, warmly supports uterine dilatation in the following instances:—1. In non-exudative pelvic peritonitis, pain which is the leading symptom can be entirely relieved. 2. In the exudative form of pelvic peritonitis, forcible dilatation by liberating the return circulation can arrest the progress of peri-uterine tumefactions, and facilitate the reabsorption of any exudation. 3. In cases of peri-uterine or pelvic abscess, which as a rule are only cysts of the fallopian tubes, the uterus being dilated, may be curetted, and the contents evacuated by the uterine canal. 4. In cases of puerperal septicæmia, the septic symptoms will rapidly disappear under this treatment; no other is so efficacious for the complete disinfection of the cavity of the uterus, which is a true nursery or manufactory for microbes. 5. Reflex symptoms, such as vomiting, are instantly removed by forcible dilatation of the uterine muscle. Thanks to rigorous antisepticism, this treatment may be considered harmless.

Consanguinity (*Journal de Médecine*).—Dr. Heliot writes as follows: It is known that the question of consanguinity has divided hygienists as well as anthropologists. It is found to be the origin of all the social groups which survive in the present day. Without going outside France there are hamlets, villages, and entire islands where relatationship is very general amongst the population, and where marriages betwixt relations in every degree does not prevent the race from prospering; but, on the other hand, it seems that family life like individual life is limited; and when we see whole races die out and become extinct, it seems that this arrest of human life extends to races as well as to families and individuals, a fact which does not, however, prevent heredity from transmitting both good and bad qualities. It is better that two vigorous cousins should be united than two puny strangers, and if families have degenerated through the subordination of the interests of health to the interests of fortune, by associating in this matter of marriage inheritance or names, when it would be of greater importance to provide for the future vitality and physiological state of the infants. There are, nevertheless, some who prosper by the same proceeding, providing those united are not monsters, idiots, or valetudinarians. He (Dr. Heliot) commenced the study of consanguinity in his father's practice, who had at an early period pointed out the dangers which attend consanguineous marriages; it is not without reason that he insists upon the authority derived from an extensive general practice to enable one to judge of the value of an opinion which had been affirmed by popular tradition, before being formulated by scientific bodies. Of the causes which lead to consanguineous marriages; difficulties of communication, sentimental feelings, and considerations of fortune appear to him superannuated and not commendable. He confines consanguinity within the sixth degree of relationship, and examples taken from an entire race—say, for instance, the Jewish race—appear to him rather to obscure than to throw light upon the question. There is a long list of diseases and infirmities which have been attributed to consanguineous marriages; such marriages may be considered as accentuating heredity, and searching out defective peculiarities, much, as zootechnic selection, brings out other qualities. Learned men have not been wanting to throw light on the subject, and Dr. Heliot reviews their researches, particularly those of his colleagues and of contemporary medical men. Personally he has sought out the causes of the prohibition which law and religion have established, at least in some countries. He does not think that legislators have been concerned solely with moral order. He treats with very little respect arguments founded on anthropology, remembering that the Jews, so often in opposition to his theory, furnish a larger proportion than other races of deaf mutes, imbeciles, idiots, etc. This result, according to Dr. Heliot, is not due, as might be thought, to the defective hygienic conditions under which the Jews live in all latitudes, but only to their consanguineous marriages. Passing to zootechnic proofs, Dr. Heliot rightly affirms, selection, as it is understood by breeders, has for its chief object to develop certain well-defined qualities, which are advantageous from a commercial or industrial point of view, but which are equally so in regard to the perpetuation and the vigour of the race. Statistics can alone decide this question, but statisticians are not agreed amongst themselves, besides which the statistical methods adopted are themselves open to objection. The impression which results from the examination of documentary evidence is that the amount of evidence is insufficient. Dr. Heliot's personal observations amount to fifty-three, which he deals with at length, and of those who condemn and those who approve of consanguineous marriages, he agrees with the former; he will not admit that toleration of them should extend in our social life in the case of infirmities and diseases. The utility of restricting the transmission of recognised evils, such as consumption, cancer, epilepsy, and insanity, should be recognised. "Individual liberty," says Dr. Heliot, "is a very good thing, but like everything else, should be subordinated to social well-being." He

hopes that those who have the best interests of family life and of society at heart will always exert themselves in opposition to consanguineous marriages.

A Man with a Tail (*L'Union Médicale*).—Dr. Piaturtsky has recently been consulted by a peasant, aged twenty-three, for a soft cylindrical tumour, seven centimetres long, and two centimetres in diameter, covered with hair, and presenting all the outward appearance of a tail; it seemed to be a prolongation or a continuation of the coccyx. This growth was amputated and examined. It consisted of a stroma of connective tissue, having blood vessels and nerves, and three layers of muscular tissue disposed in three bands. Many of the fibres had undergone fatty degeneration, and it was concluded that the atrophy resulted from disuse. The presence of muscular fibres, is enough to prove that the growth was a true congenital tail, and not simply an excrescence of the skin simulating a tail.

Treatment of Hydatids of Liver (*L'Union Médicale*).—Dr. Debove, notwithstanding that the progress of antisepticism has minimised the danger of laparotomy, prefers a simple puncture, followed by injection in the great majority of cases of hydatid disease of the liver. He describes two recent cases in which a cure had been obtained by simple puncture, evacuation of the fluid contents, and an injection of the sac of Van Swieten's fluid, or of a five per cent. solution of sulphate of copper, which was withdrawn after an interval of a few minutes. In one case erysipelas followed, and the high temperature may have contributed to the ultimate destruction of the hydatids.

III.—NOTES FROM RUSSIAN, POLISH, AND SWISS JOURNALS.

By VALERIUS IDELSON, M.D., BERNE.

Creolin as a Remedy for Ulcers and Wounds.—In the *Berliner Klinische Wochenschrift*, No. 46, 1887, and later on in the *Centralblatt fuer Gynecologie*, No. 6, 1888, Dr. Kortüm has published three articles in which he highly eulogises a new disinfecting compound patented by Messrs. W. Pearson and Co., of Hamburg, under the name of "creolin." According to the patentees' assertions, their mysterious preparation represents "a product of dry distillation of British coal of a peculiar kind." In the *Pharmaceutische Centralhalle* (No. 37, 1887), however, another well-known German firm, named "*Eisenbuettel's Chemische Fabrik*," has at once flatly declared that the so-called "creolin" is quite identical with the "sapo-carbolum crudum No. 2," issued by the firm in 1884, and representing nothing else than a solution of common green soap in crude carbolic acid, the difference consisting, in fact, solely in the price. While Pearson's "creolin" is sold at 200 marks per 100 kilogrammes, Eisenbuettel's "crude sapo-carbolum" costs only thirty-three marks for the same weight. However it might be, Dr. Kortüm has found the substance a most excellent disinfecting and antiseptic means both in surgical and obstetrical practice, while Dr. Froehner (*Archiv fuer Wissenschaftliche and Praktische Thierheilkunde*, 1887, vol. xiii., p. 341) has obtained from creolin best possible results in scabies, eczema, infectious bronchitis, broncho-pneumonia, gastro-intestinal catarrh, and other affections in lower animals. To verify these assertions, Dr. Josef F. Zemacki (proun., "Zematzkee," a Polish name) house-surgeon to the Obükhovsky Hospital, St. Petersburg, has undertaken (*Khirürgitchesky Vestnik*, Sept. and Oct., 1888, p. 586), at Dr. A. A. Troianoff's suggestion, a long series of clinical experiments on the creolin treatment of ulcers of various kinds, and wounds. A genuine preparation, obtained from Messrs. Pearson and Co., was used for the purpose. In every one of the author's cases, the parts affected were covered with a piece of common gauze soaked in a two-per-cent. aqueous emulsion of creolin, above which compress either a wax-paper, or tar-tow, or a moss-bag, was placed, the dressing being changed at first twice daily, but on later experiments only once every two days. Dr. Zemacki's conclusions may be briefly summed up as follows: (1) In unclean, deep gangrenous ulcers, with offensive flocky discharge, spongy bottom, and undermined or lacerated edges, creolin proves to be, undoubtedly, an excellent deodorising means, the odour strikingly decreasing after a single washing out with the solution, and disappearing altogether after a few compresses. Under the influence of the latter the ulcer rapidly becomes cleaner and covered with more or less profuse granulations, which, however, generally look somewhat flabby, "rather lifeless," and have a peculiar ashy-grey tint. (2) In chronic inveterated callous crural ulcers, with atonic, coarse, and sclerosed bottom, creolin is not only useless, but sometimes proves even decidedly injurious, "since it destroys the last traces of a vital reaction." The best treatment for the cases is thought to be, after all, adhesive plaster in the shape of strips. 3. In simple well-granulating ulcers, creolin acts on granulations and cutaneous surface nearly in the same way as carbolic solutions. (4) In syphilitic ulcers the drug acts solely as a deodorising and antiseptic means, but fails to bring about or accelerate their healing. The latter ensues only under the influence of usual specific remedies. (5) Creolin remains similarly ineffective in tubercular ulcers which improve under iodoform, as well as in scorbutic ones which yield to compresses soaked in aromatic vinegar. (6) In superficial cutaneous ulcers, abrasions, fissures, and similar lesions associated with intense pain, tenderness, and irritation, creoline, as an antiphlogistic or soothing means, is absolutely good for nothing. Not only redness, swelling, and pain remains unaltered, but there supervene, in addition, all unmistakable signs of an increased local irritation, the patient complaining of discomfort and painful sensations of varying description. A warming compress soaked in a boracic, carbolic, or sublimate corrosive solution, relieves the symptoms, as a rule, within twenty-four hours. (7) Similarly, in recent (surgical cut) wounds, creolin gives rise to intense, and sometimes even intolerable local burning and pain; in short, acts as a caustic means. Dr. Zemacki's general conclusion is to the effect that "as far as human beings are concerned, creolin is useful only as a deodorising agent, in which regard it may be placed on a level with Dïanin's trichlorphenol (*vide* the *London Medical Record*, April, 1883, p. 132); but the drug is entirely worthless as an antiseptic means, while, on the other hand, it possesses fairly considerable caustic properties." The latter, possibly, may be discovered also in Dr. Zemacki's remarks, which are evidently addressed to Drs. Kortüm and Froehnel, and in which he expresses a hope that, after Eisenbuettel's declaration, "hardly anybody will go on with recommending a crude potassic green soap dissolved in a crude carbolic acid as a most splendid antiseptic means." The author expects, on the whole, that "a more or less suitable place for creolin might be yet found in veterinarian practice, but by no means in that amongst some higher animals."

Hypodermic Injection of Antipyrin and Cocaine in Sciatica.—Following the instance of Professor Germain Sée, of Paris, Dr. Lazar I. Osherovsky, of Sükhüm-Kalë, Kütaïs Government, treated (*Proceedings of the Caucasian Medical Society*, June 13, 1888, p. 83) four cases of severe sciatica by the hypodermic injection of antipyrin with cocaine after the following formula:

℞ Antipyrin, aq. destill. .....ana ʒ j.
Cocaini. hydrochlor .....gr. ss.

M.D.S.—To inject under the skin from ten to sixteen drops (*i.e.*, from five to eight grains of antipyrin and from $\frac{1}{12}$th to $\frac{1}{8}$th of a grain of cocaine) once daily.

The solution was injected very slowly and deep into the femoral cellular tissue, the injection being followed by firmly rubbing the parts for three minutes. In one case referring to a robust lady of fifty, with an intense rheumatic neuralgia of the left thigh, the very first injection brought about immediately a striking relief, a complete and permanent recovery ensuing after five sittings. In another patient, an emaciated male peasant of thirty-five, with an incessant (day and night) agonising pain along both his lower limbs of three and a half months' standing, and of a rheumatic origin, cure followed after twelve injections (five into the left thigh, seven into the right one). In a third case, in that of a retired ship-master, aged fifty-two, with rheumatic left-sided sciatica of two years duration, the injections brought but a temporary relief, a permanent recovery taking place only after a month's faradic treatment. The fourth case refers to Dr. Osherovsky himself, who had frequently been suffering from neuralgic pains in the whole region of the right sciatic nerve, and had recently caught a bad neuralgia from exposure. He cured himself by three injections of the solution. Having analysed his cases, and reviewed the literature of the subject, the writer comes to the following conclusions: (1) Antipyrin represents a powerful nervine remedy, which can not only relieve pain, but even cure neuralgia. (2) It has an important advantage over morphium in its being free from such accessory effects as giddiness, sickness, drowsiness, general excitement, and other symptoms which are apt to follow the administration of morphium. (3) A hypodermic use of the drug should be preferred to an internal one, since (*a*) the former requires smaller and less frequent doses comparatively with the latter, and (*b*) when injected under the skin, the drug soothes pain far more rapidly than when given internally.

[Referring to Dr. Osherovsky's statement *sub* 2, Dr. E. P. Gaüdelin, of Tiflis, says (*l. c.*, p. 89) that antipyrin is not altogether free from unpleasant accessory effects. For instance, he happened to see a case where a single five-grain dose of the drug, taken internally by a nervous, but otherwise quite healthy lady, gave rise to an alarming swoon which lasted for several hours, notwithstanding the administration of stimulants and analytics. Hence it is advisable to "begin always with small doses in order to previously determine an individual reaction of the person given."—*Reporter.*]

Acute Muscular Atrophy following a Traumatic Injury to the Head.—In the Polish *Przeglad Lekarski*, July 14th, 1888, Dr. Idzinski adduces a remarkable case of acute organic atrophy of several muscles,

caused apparently by some traumatic lesion of the brain. The patient, a previously healthy soldier, æt. twenty-four, received a violent blow on his vertex from an unknown person and by an unknown weapon, the affair occurring one dark night. The patient did not lose consciousness, and even was able to run after his assailant. The wound inflicted was situated in the right parietal region, two centimetres from the saggital suture, and three from the frontal and parietal tubers, only the scalp being injured. In the period of its healing the man experienced a pricking pain and failure of mobility about the left shoulder. On examination, about two weeks after the accident, there was found a pronounced atrophy of the left deltoid, biceps, supraspinate and infraspinate muscles, the remaining muscles of the body being well developed and healthy. Of all active movements of the left shoulder joint, only lifting up the extremity was preserved. Sensibility, internal organs, in fact everything beside the said muscles, were found normal. Dr. Idzinski thinks that the wasting resulted from "some molecular change in the corresponding motor area of the brain." The case is said to be yet unique.

On Hæmorrhagic Infections.—Basing his statements on ten fatal cases examined anatomically and bacterioscopically, Professor Jaroslav Hlava, of Prague, in Bohemia, says (*Wiadomosci Lekarskie*, August 1888, p. 54) that in an overwhelming majority of cases, hæmorrhagic infection represents only a secondary phenomenon, caused either by the sterepto-coccus or by the *bacillus septico-pyæmicus*. In some rare cases, however, there can arise an *infectis hæmorrhagica primaria*, which is then to be regarded as "a severe intoxication caused by microbes of putrefaction (*microbe guilne*).

Cæsarean Section at Cracow.—At the recent general meeting of practitioners at Lvov, in Austrian Galicia, Dr. Stanislaw Braun, of Cracow, has read (*Wiadomosci Lekarskie*, August, 1888, p. 67) an interesting paper on the only three cases of Cæsarean section performed in Professor M. Madurowicz's clinic during the last eighteen years. In the first case (1870) the operation (after the classical method) was resorted to on account of an enormous tumour, connected with the right crural nerve, firmly adherent with its surroundings, and filling up the whole minor pelvis. The (asphyctic) fœtus was resuscitated, but the mother died from hæmorrhage and peritonitis three days later. The other two cases (1887) refer to dwarfs with a generally narrowed, flattened, and scoliosed pelvis, in one of whom Porro's, and in the other Saenger's operation was performed, both the mothers and infants remaining alive and sound. In the case operated upon after Saenger's plan, the uterine wound was closed with three *etage* sutures (stout chromicised catgut, No. 3), the patient leaving in best state about the sixth week after the operation.

Gastric Hæmorrhage Caused by Embolism of the Gastric Arteries.—At the meeting of the Gesellschaft der Aerzte, in Zurich, Dr. Hermann Mueller has communicated (*Correspondenz Blatt fuer Schweizer Aerzte*, November 1st, 1888, p. 667) an extremely rare case of the kind. A habitually rather anæmic, but otherwise fairly healthy man, aged fifty-seven, applied to Dr. Nuescheler on account of acute dry bronchitis. Three days later, in the morning, there appeared quite suddenly nausea, intestinal tenesmus, and a profuse vomiting with blood, the patient swooning close to his bed. At noon, and about ten p.m., the attack recurred, an enormous quantity of blood being ejected each time. For the following three days the patient's state somewhat improved, the only symptoms being an extreme burning and intolerable headache with abdominal pains. On the fourth day, the morning temperature rose up to 38·6° C. Dr. Mueller having been called for consultation, both the doctors came to the conclusion that the patient was suffering from a gastric ulcer, which up to the present had been running a latent course. On the 5th day, a deep swoon suddenly occurred, the patient lying quietly in bed at the time. On the sixth day he died. At the necropsy, the stomach and small bowel were found distended with blood-clots, the mucous membrane in the pyloric half of the organ being of a dark blue-red colour and studded with ecchymoses. The left kidney contained a recent hæmorrhagic infarctus of the size of a cherry. The heart was flabby, but its valves presented nothing abnormal beyond a few small sized atheromatous patches. In the aorta, however, especially in its ascending portion, there were scattered several atheromatous ulcers, of which two were covered with rather old, firmly adhering fibrine deposits. The latter, undoubtedly, represented the source both for the renal and gastric embolism.

Professor Nasïloff on Hot Compresses in Surgical Practice.—In the *Vratch*, No. 42, 1888, p. 825, Professor Ivan I. Nasïloff, of St. Petersburg, writes that he has treated by scalding hot compresses (*a*) five cases of chronic scrofulous disease of cervical or axillary lymphatic glands; (*b*) two cases of rheumatic osteo-myelitis of the humerus (near the shoulder-joint); and (*c*) two cases of fungous arthrophlogosis of the knee-joint. The mode of application was invariably this. Having soaked a compress (a linen rag of sufficient size, folded four times) in a mixture consisting of equal parts of ordinary water and a Staraia-Rüssa saline brine, and having the temperature of from 70° to 80° Reaum., he swiftly wrung out from it any excessive fluid, and spread it over the region affected, and, to prevent cooling down, covered the compress with a thick layer of cotton wool, the temperature under the dressing (that is, between the compress and the part) varying between 45° and 65° Reaum. As soon as a very lively burning pain commenced to vanish, which usually occurred in two or three minutes, another compress was similarly applied, to be replaced by a fresh one in as many minutes, and so on, for fifteen minutes at a sitting, twice daily (morning and evening), during the interval the part being kept wrapped in cotton wool. The inferences drawn by Professor Nasïloff from his clinical experiments may be summed up as follows:—1. Hot water compresses produce intense redness, and even blistering—that is, the first and second degrees of scald—of the skin. 2. At the same time, they most distinctly act also on deeper situated structures. 3. In cases of scrofulous lymphatic inflammation, they fairly rapidly induce disintegration of glandular masses with a temporary increase of suppuration. 4. Neither the cutaneous changes, nor initial rather profuse suppuration do contra-indicate a further use of hot compresses. In course of time, purulent discharge from sinuses becomes scantier and ceases altogether, purulent accumulations are re-absorbed, glandular tumours strikingly decrease in their bulk, etc. 5. The earlier hot compresses are resorted to in scrofulous inflammation of glands, the sooner they commence to manifest a distinctly beneficial influence on the disease. 6. Hot compresses are, most decidedly, of great service also in rheumatic osteomyelitis, and even in fungous disease of joints. [In the author's osteo-myelitic cases, a complete and permanent recovery was obtained after a course of two and a half months' duration; in the arthritic, after that of three weeks, respectively forty-three days.] 7. The re-absorption of inflammatory products is always accompanied by febrile movements of varying intensity, the evening temperature rising sometimes up to 39° C., but usually oscillating about 38° C. 8. The temperature seems to oscillate the more intensely, the more numerous the inflammatory foci are which are undergoing re-absorption. 9. The more markedly inflammatory swelling decreases, the more intense the oscillations become. 10. Both the pyrexia and defervescence (after the discontinuance of the treatment) present individual variations in regard to time, in the sense that in some cases they occur relatively early, in some comparatively late. It appears, however, that the longer the duration of the treatment is, the more slowly the temperature returns to the standard. 11. Be the thermic oscillations rather considerable, the treatment must be discontinued for a while, until the temperature regains its normal condition.

[Leaving aside everything in regard to actual therapeutic merits of Professor Nasïloff's treatment, we cannot help observing that the distinguished surgeon's method presents an exceedingly grave drawback in its being cruel, if not barbarous, since it is, in fact, nothing else than deliberately scalding the patient for a quarter of an hour twice daily, with usual consecutive incessant pain and discomfort during the intervals between the morning and evening tortures. In so far, this "hot" plan obviously stands in an utter opposition towards modern "humanising" tendencies of our healing art, which strives to find out such methods for relieving the sick fellow-man's sufferings as do not involve any additional pain, or even discomfort. The patient's ideal subjective well-being must ever be one of the aims and guides of our behaviour all through, in accordance with "the great ethical principle of our profession—that we should endeavour, as far as lies in our power, to preserve life as well as alleviate pain" (see Professor Victor Horsley's most admirable paper in the *British Medical Journal*, June 9th, 1888, p. 1211). Any such methods for "relieving" the patient's sufferings as inflict additional pain are, undoubtedly, violating the said principle. *Vide* also the PROVINCIAL MEDICAL JOURNAL, July 2nd, 1888, p. 323.—*Reporter.*]

On Perforating Intestinal Ulcers.—In the *Vratch*, No. 40, 1888, p. 788, Dr. Vladimïr F. Büshüieff, of St. Petersburg, details an instructive case of a strongly made and previously quite healthy daily labourer, æt. seventy-three, who, when trying to lift up a heavy palliasse one evening, had suddenly felt an acute violent pain about the right side of his abdomen, followed by a deep swoon of ten or fifteen minutes' duration, and later on by severe vomiting and diarrhœa. When admitted to Professor D. I. Koshlakoff's clinic on the next morning, he was suffering from agonising abdominal pain and tenderness, extreme general prostration, tympanites, fever—in short, presented all symptoms of acute general peritonitis. About forty-eight hours after the first symptoms he died. At the necropsy, the peritoneal cavity was found to contain a moderate quantity of a yellow, turbid fluid with a fæcal odour. Intestinal coils were glued together with recent fibrinous pseudo-membranes,

the gastric mucous membrane being tumefied and studded with red and black patches of varying size, while the intestinal canal was anæmic and rather flabby. On the mesenterial aspect of the jejunum, ten feet from the ileo-cæcal valve, there was situated longitudinally an irregularly oblong perforating ulcer, measuring seven millimetres in length and three in maximal breadth, and containing a small-sized fish vertebra fixed with its sharp curved ribs at the extremities of the perforation. The foreign body could be freed without the slightest difficulty. Analysing his case, Dr. Büshüieff dwells mainly on the following points of considerable practical interest:—1. The peritonitis obviously resulted from perforation of an ex-ulcerated bowel, while the ulceration, in its turn, had been caused by the presence of the fish bone, swallowed during a hearty meal. In common with many British and American clinicists, Professor V. A. Manasseïn has been for many years past emphatically drawing attention to the fact that a hasty and generally imperfect mastication of food does play a very important *rôle* in the development of dyspepsia and catarrhs. Dr. Büshüieff's case points out that a neglectful performance of the act can lead even to intestinal ulceration with a fatal issue. It might seem quite superfluous to insist on so trivial a point as that everybody (as well as "everybody's wife and children," of course) must chew his food most thoroughly. However, the matter is still utterly neglected by the laity, and that not only by so-called "lower," or "ignorant classes" (which, being simultaneously hard working classes, have but very little time for their meals), but even by "higher," or "educated society." As Professor Koshlakoff states, those "betters" are "usually taking their meals so incautiously that they often manage to swallow a wood-hen's clavicular arch in its intact state."

2. Had no accidental perforation of the bowel, but only a superficial extension of the ulcer, occurred in the case above, the foreign body might easily become free and be ultimately expelled *per anum*, leaving then a lesion which on the necropsy would be undoubtedly placed amongst the category of "intestinal ulcers of an unknown causation," the group which, as far as duodenal ulcers are concerned, embraces as many as 33.7 per cent. of all cases of the lesion (according to Dobroklonsky's statistics; *vide infra*). Hence, a supposition naturally arises that many intestinal as well as gastric ulcers of the said obscure category can actually derive their origin in the mucous membrane being wounded and irritated by various foreign bodies (such as bones, small-sized sharp stones, glass splinters, etc.) which, having been swallowed, get entangled between some folds of the gastro-intestinal mucous membrane. The fact that some more or less biggish foreign bodies (money-pieces, etc.), when swallowed by the patient, may not unfrequently pass through his digestive tract *apparently* without any harmful influence on the latter, cannot possibly speak against the hypothesis, since "in such cases, nobody can either assert or deny that they *actually* leave no traces or injuries in their passage through the patient's stomach and bowels." As a matter of fact, "peptic ulcers" may run their course quite latently for a prolonged period, and even may completely heal through cicatrisation.

3. The traumatic hypothesis furnishes a satisfactory explanation for certain clinical facts which otherwise remain quite mysterious. Thus, it is well known that peptic ulcers occur most frequently in the stomach and commencement of the duodenum; less frequently, about the middle and terminal portions of the latter; and by far still more rarely in the jejunum and ileum. That order of frequency may be explained, Dr. Büshüieff thinks, simply by this circumstance, that the stomach and upper portion of the intestinal tract are wounded and irritated by foreign bodies, naturally, earlier, and more frequently than the lower portions of the tract. Further, it is familiar with all that in children peptic ulcers are met with but exceeding rarely, comparatively with adults (according to Brunton, infantile gastric ulcers constitute 0.8 per cent. of all cases of the lesion; according to Dobroklonsky, only 6.3 per cent. of all cases of duodenal ulcer refer to children). Dr. Büshüieff supposes that the relative immunity may be ascribed to the circumstance that children's feeding is comparatively better attended to (in mechanical regards), even amongst the lower classes of the community, since the surrounding adults, usually, are anxious to prevent the child's choking and such like accidents.

The traumatic hypothesis throws some light on Dr. Eduard Sperk's observations (*vide* the *Lovtzoff's Medico-Topografitchesky Sbornik*, 1870, vol. i., p. 18), according to which gastric ulcer is spread exceedingly widely amongst the inhabitants of the Okhotsk and Gÿghïnsk districts (situated in East Siberia, along the coast of the Okhotsk Sea), whose staple food article is fish; while amongst the population of the neighbouring Amür District where there largely prevails a vegetable dietary, the ulcer represents a but very rare occurrence (*ibid.*, p. 29). The hypothesis helps us to understand also why an imperfect mastication appears to have an important significance in the etiology of gastric ulcer, as Professor H. Eichhorst, of Zurich, points out.

[In the *Ejenedelnaia Klinitcheskaia Gazeta*, Nos. 21 and 22, 1886, p. 300, Dr. V. P. Dobroklonsky, of St. Petersburg, publishes a case of perforating ulcer of the duodenum, near the pyloric valve, referring to a labourer of sixty, and ending in death from fulminant general peritonitis. Having reviewed international literature, the author was able to collect 190 cases of duodenal ulcer (of these about fifty from the Anglo-American literature). The following results of Dr. Dobroklonsky's statistical inquiry deserve to be placed before our readers. 1. *Sex.*—Of 184 cases, 142 (77.2 per cent.) refer to male patients, and only 42 (22.8 per cent.) to women. 2. *Age.*—Of 171 cases, 32 refer to the age between 30 and 40; 31 to 50-60; 23 to 40-50; 20 to 20-30; 18 to 10-20; 17 to 60-70; 12 to 1-10; 6 to 70-80; 2 to 80-90. 3. *Etiology.*—Of 95 cases, in 32.6 (33.7 per cent.) nothing abnormal beyond a duodenal ulcer, could be detected by a most careful examinaton; of the remaining 63 (66.3 per cent.), in 17 (17.9 per cent.) there was found, besides the ulcer, some morbid lesion of the heart or large arteries; in 25 (26.3 per cent.) pulmonary affections (in 20 chronic pneumonia); in 3 (3.2 per cent.) pleurisy; in 1 (1.1 per cent.) peritonitis; in 21 (22.1 per cent.) hepatic disease; in 17 (17.9 per cent.) renal; in 5 (52.5 per cent.) gastric; in 2 (2.2 per cent.) pylephlebitis suppurativa; and in 2 (2.2 per cent.) gall-stones in the gall-bladder. 4. *Anatomy.*—Of 137 cases, in 125 (91.4 per cent.) the ulcer was situated in the upper horizontal portion of the duodenum; in 10 (7.3 per cent.) in the descending; and in 2 (1.4 per cent.) in the lower horizontal. Of 58 cases of an upper horizontal ulcer, in 22 (37.9 per cent.) it was situated on the anterior wall; in 28 (48.3 per cent.) on the posterior; in 4 (7.4 per cent.) on the upper; and in 4 (7.4 per cent.) on the lower. 5. *Symptomatology.*—Of 190 cases, in 25.8 per cent., the course of the disease was perfectly latent up to a final development of perforative peritonitis, or up to the patient's death. In 47.5 per cent. there were present anorexia, eructations, nausea, vomiting with food, mucus, and gall; in 18.3 per cent. hæmatemesis; in 9.2 per cent. blood-stained stools; in 10.8 per cent. jaundice; in 49.2 per cent. abdominal pain. 6. *Issue.*—In 65.8 per cent. death followed from perforative peritonitis, and in 22.5 from hæmorrhage (either from the duodeno-pancreatic artery, or even from the aorta), while the remaining patients either died from exhaustion, or—very rarely—recovered, to die subsequently from secondary cicatricial stenosis of the duodenum.—*Reporter.*]

IV.—PUBLIC HEALTH.

Dr. Whiteside Hime on Milk in Relation to Scarlatina.—In the recent report issued by the Privy Council, "On the Eruptive Diseases of the Teat and Udders of Cows in relation to Scarlet Fever in Man," prepared by Professor Brown, the following observations by Dr. Whiteside Hime are included:—

"A new and mainly economical difficulty has arisen from the reported danger of the infection being spread by milk. The seriousness of the loss inflicted on farmers and milk dealers by the mere suspicion that their milk may be infected is very great, the sale of milk being almost the sole source of income of the milk seller. But when in addition to the loss thus inflicted by suspicion aroused in the public mind there is added the authoritative dictum of the sanitary authority or of medical officers and practitioners of repute that scarlet fever in a particular district has actually been caused by infected milk, then, indeed, the milk dealer's cup may be said to be full, his business is ruined, and thousands of gallons of milk are condemmed as being dangerous to the health and life of the consumers. A very uneasy feeling as to scarlet fever has undoubtedly prevailed for some years among the general public and the more active sanitary authorities throughout the country, to say nothing of those who have been suspected and even definitely charged with having spread broadcast the specific infection of so dire a disease in the carrying out their commercial undertakings. Hence the announcements that 'the essence of the disease' had been discovered, and that skilled experts had tracked it to its very source and primal origin, at once interested the public as well as the official sanitary world. That so much had been done in this direction with reference to Asiatic cholera, fowl cholera anthrax, and other diseases of much less direct and serious import to the inhabitants of this country, had often been referred to in a reproachful way, as militating against the practical value of bacteriological research. But here at last was a discovery with regard to one of the most prevalent aud most dreaded of the diseases of everyday occurrence. Naturally great expectations were excited from the announcement that the first essential step towards the prevention of scarlet fever had been successfully made in the discovery of the specific organism to which the disease is due. Professor Klein's statements on the subject are sufficiently explicit and detailed, and he alleges that the micrococcus scarlatina has been found, he describes it 'morphologically distinguishable from any other known form of micrococcus,' and 'has a definite mode of

existence of its own.' Further, his report states that calves inoculated with the blood of human beings suffering from scarlet fever, and also with artificial cultivations of the micrococcus taken from human patients with scarlet fever, developed the same symptoms as were shown by the original animals of Hendon, and the micrococcus, 'the essence of the disease,' was found in their blood and other tissues. Subsequently, some condensed milk, suspected of having caused scarlet fever, was found by Professor Klein to contain a micrococcus 'which, in its morphological and cultured characters, bears a striking resemblance to the micrococcus scarlatinæ of the Hendon cows and of human scarlatina.' Inoculation of calves with the micrococcus produced the characteristic symptoms in the animals, and led to the reproduction in them of an organism identical with that inoculated. Scarlet fever has always been regarded as an eminently contagious disease, transferable from the sick to the sound by immediate and mediate communication; by direct contact, through the medium of infected air and by the agency of infected articles, such as clothing. In the vast majority of cases there is little difficulty in ascertaining the source of infection. But at times the most persevering investigation fails to suggest when the danger has arisen, and the baffled inquirer has been fain to assume a cause, unless indeed he possessed that quality so invaluable to the scientific inquirer, namely, the moral courage to admit his inability to assign a satisfactory origin of the disease. . . . . The circumstances connected with the serious prevalence of scarlet fever in Bradford during 1887 were certainly not such as to warrant the assumption that infected milk was the cause, or even an accessory agent. The reader, however, will judge for himself. The evidence is simple in character, and very large—larger, indeed, in one respect, and more complete, than in the case of any of those towns where epidemics of scarlet fever have been attributed to infected milk with which I am acquainted. I refer to the important fact that I was aware not only of those cases in which certain individuals acquired scarlet fever who drank milk from the suspected source, but I also know all the cases which did not take it, although drinking from the same can. And no less important is the additional fact that I not only knew the cases of scarlet fever which occurred among the customers of a particular dairy, but I knew every case of scarlet fever in the town. The notification of cases of infectious diseases has been compulsory in Bradford since 1881, and is carried out with great loyalty and punctuality by the medical practitioners of the town. In addition to the important information furnished by means of notification, I was also enabled, under a local Act, to obtain the full list of names and addresses of all the customers of any milk seller in the town with regard to the character of whose milk there was any ground for suspicion. So far as I am aware, such full information was not in the possession of any of those who have reported an epidemic of scarlet fever as being due to milk, or, as it has become the fashion to term it, 'milk scarlet fever,' the assumed cause of the disease being asserted by the significate terminology. Indeed, it is a notable lacuna in the evidence in these reports that usually only those cases of scarlet fever, are known which happened to be among the customers of a particular dairy, while nothing is known or reported as to the existence of the disease, possibly prevalent in much more extensive form, among those who were in no way connected with the condemned milk supply. This serious defect in the evidence in such cases must strike every impartial inquirer. It might be perfectly true that a large number of persons infected with smallpox in a certain town banked at the same establishment, and a hasty conclusion might be adopted in consequence that 'in some mysterious way' (to quote the words of the author above referred to) the disease was connected with the bank. But further inquiry might show that not only the clients of this bank, but persons not banking accounts at all, were suffering from the same disease. The absurdity of the conclusion which convicted the bank as the source of the disease is plain enough. But the same error has been frequently committed with regard to scarlet fever, the method of argument being as follows:—Some of the customers of a certain dairy or even many of them have scarlet fever, therefore, the dairy is, 'in some mysterious way,' the cause of the disease. That the dairy is at fault is assumed; and even it, as in the case referred to already, the cows are manifestly healthy, and the dairy-folk are perfectly free from suspicion of disease, all the same the dairy is declared to be the source of the disease! The existence of scarlet fever in other parts of the town, although in itself quite sufficient to account for the cases among the customers of the dairy, is ignored altogether; and the possibility of the infection having been acquired from them is never entertained. Even casual inquiry will show that many of the inhabitants of the same streets or districts usually obtain their supplies of food, clothing etc., at the same store. There would not be the least difficulty in proving that of a certain number of persons suffering from scarlet fever, or bronchitis, or pluerisy, or broken legs, a considerable number dealt with the same baker, or fishmonger, and beyond all doubt the same chemist would be found supplying a large number of such sufferers with physic. At the same time it would be found that the customers of other bakers, grocers, chemists, etc., were not so suffering. Hence it might be argued that the patients were infected by the shopkeepers in question with whom they dealt. As a fact, the great bulk of the cases of scarlet fever in Bradford were attended by a few medical men, while a large number had not one patient. If compulsory notification had not been in force here, an inquirer might have discovered this fact: that while Doctor A had forty cases of scarlet fever under his care, Dr. B had not a single patient. Would he on this account have been justified in concluding that Dr. A was the source when the disease spread? But this is exactly the argument used to convict the milk seller. The customers of the dairy are found to be suffering from scarlet fever, while the customers of another escape, *therefore* the first dairy caused the disease! This is not a suitable place to discuss the purely scientific aspects of the supposed discovery of 'the essence' of scarlet fever, or of the general evidence on which the convictions of the cows at Hendon of being the originators of an outbreak of human scarlatina rests. There are, however, several weak points in this portion of the case. But the matter is of such vast importance, and the consequence of the acceptance of a false theory are likely to be so disastrous, that I think it well worth while to give the outline of an experience on the largest scale hitherto recorded, so far as I am aware, in any one place in reference to epidemic scarlet fever and milk. It may be well first to ask whether it is not remarkable that the disease of the Hendon cows, the alleged cause of human scarlet fever, is only known to veterinary surgeons, farmers, and those who are familiar with cows as common cowpox. Scarlet fever has been known for ages, and it is unfortunately a familiar disease pretty well all over the globe. If there is a disease in cows, as asserted by Professor Klein, which is a source of so common and widely-spread a disease as human scarlatina, surely it must have been met with and recognised at some time and place, or even, one might expect, in very many places and on many occasions. It is quite certain that some of the most distinguished veterinary surgeons of this country and of the Continent are entirely unacquainted with the disease. In our Bradford experience it will be found that not only have there been cases of scarlet fever among persons using a common milk-supply which was free from infection, but that still large numbers drunk milk from an infected dairy without the slightest evidence of their having suffered any detriment. In no case was there any disease, either internal or external, among the cows, nor could the most minute examination detect any trace of skin disease in any part of the body. And, further inquiry failed to elicit any evidence that they had suffered in health, or exhibited any of the well-marked symptoms of 'the Hendon disease' prior to the investigation. Scarlet fever has been prevalent in Bradford for several years. In 1887 it assumed the proportion of a severe epidemic, which reached its height towards the autumn. During the year there were no fewer than 1308 cases notified," Dr. Hime then proceeds to give cases in support of his statements, and presents a summary of the facts related in tabular form, which shows that in six cases the milk was supplied to eleven public-houses, clubs etc., to 797 families, and to 3985 individuals, and that there were nine cases of diseases at the milk sellers', and fourteen cases among the consumers (thirteen scarlet fever and one typhoid). Dr. Hime then proceeds:—"I think that after a perusal of these cases it would hardly occur to the mind of anyone who was not familiar with the theory of milk infection, that any of the four cases of scarlet fever which occurred among the customers of the milkmen who had scarlet fever in their families were infected by the milk, or by the retailer of it. Indeed, when we find that three of these cases of scarlet fever (No. 4) occurred nearly three months after the milkman's child became ill, and the fourth (No. 5) also after an interval of nearly three months, the supposition loses all probability. But when we find that seven cases of scarlet fever occurred in the families of milk sellers without any case arising among the customers, it becomes all the more difficult to suppose that any of the other four were infected in this way. Finally, when we consider the dates when these four cases occurred among the customers of the infected dairies, it becomes absolutely impossible to believe that they were caused by the milk." After some general observations on the cases related, Dr. Hime concludes as follows:—"It may be urged that at least my facts are but of negative value, and only prove that in Bradford in 1887, the epidemic was not propagated by milk. From the nature of the case no other evidence could be offered. But evidence proving the prisoner did not commit the crime positively establishes his innocence. It seems to me that every condition favourable to the infection of the milk existed in Bradford, and yet it escaped. Could any conditions be devised or demanded more calculated to secure the infection of the milk of No. 6? Compare the circumstances of this case with the ordinary run of reports of epidemics attributed to milk, in which the dairy is condemned merely because there were suspicious symptoms observed in some of the inmates, or in consequence merely

of the fact that the consumers of the milk of that dairy had scarlet fever, while others escaped. If the consumers of the milk of No. 6 had suffered severely from the scarlet fever, would there not be a consensus of opinion declaring that the milk was the cause? If under these very favourable conditions the milk and the cows escaped infection, is it not much more probable that there must be the greatest difficulty in its ever becoming infected? Personally, I neither deny nor affirm the *possibility* of the conveyance of the infection of scarlet fever by milk. I, however, am quite unable to admit the validity of the arguments by which, as a rule, this view is supported, and I am satisfied that it is not applicable to the circumstances of the epidemic of Bradford in 1887. To trace infection to its source is a most difficult matter, but neither truth nor science is served by bridging the distance by a pile of assumptions."

V.—THERAPEUTICAL NOTES FROM FOREIGN JOURNALS

Codeia in Diabetes (*Revista Argentina de Cientias Médicas.*)—A patient, in whom large quantities of sugar persisted in the urine, despite the employment of all known remedies, was given codeia, which has been so highly recommended by Lauder Brunton in such cases, and the effect resulting on its use was apparent immediately. After its use for one week thirst, hunger, and excretion of sugar had ceased. The improvement continued in spite of the discontinuance of the drug, and on the appearance of a relapse after several months the symptoms again entirely disappeared after three days' use of large doses of the codeia. The author adopted this mode of treatment after this result in twelve other cases of diabetes mellitus, with the following result: Cured, 7; improved, 2; not benefited, 1; died, 2. Of the two last-named cases, the one was the most severe case of diabetes he had ever seen, while the other, while really in a fair way of recovery, succumbed to a severe pneumonia which he had contracted. The mode of treatment was, in general, about the following: One grm. of codeia was directed to be divided into twenty pills, of which the patient was given three the first day. If these were well tolerated, without headache or over-much sleep, etc., he was directed to take one more pill the following day, and if the tolerance continued a second pill was added on the third day, so that the patient rapidly advanced to the daily dose of 0·25 grm., the equivalent of five pills. This is about the general average quantity which one employs in the subsequent days, if tolerated by the patient and according to the symptoms of the disease, and above all being regulated by the quantity of the urine and the amount of sugar it contains, and particularly whether this be increased or decreased. The general dose of codeia gives the following results: 1. The sugar disappears completely from the urine; coincidently we have cessation of polyuria, thirst, etc., and in consequence a complete improvement of the patient, who regards himself as radically cured. 2. The sugar in the urine disappears relatively, or absolutely, according to the quantity of the secretion that is eliminated by the patient in the twenty-four hours. The improvement is not so perceptible, even when pretty well marked. 3. The sugar in the urine is not at all lessened; neither is the quantity of the urine reduced. The patient continues the use of the drug. In the first case, if the patient is cured in a few days, the author being in doubt as to the permanency of the cure, continues the treatment for another two or three weeks. Should then no more sugar appear, the number of pills daily ingested is removed by one until one pill is taken per diem. A little later this is reduced to one pill in two three to seven days, so that only one will be taken weekly, and the drug is finally dispensed with in one of the latter intervals. In the second case, when only usual improvement is attained with the general dose, one increases each week by one the daily number of pills. Great care, however, must be paid to the tolerance with which the patient bears the remedy. In rare cases only is one obliged to resort to the daily administration of ten pills (50 cgrm. codeia), for generally the sugar disappears before this, or some symptoms of intolerance appear which will not admit of farther increase of the drug. The latter appearances were only once manifested to the author. If now the patient has completely improved, one continues, as in the first instances, and combines the codeia with other remedies, among which we enumerate Turkish baths, massage, gymnastics, alkaline, mineral waters, and an animal diet. In the third case, if the patient does absolutely not improve, one increases the dose of the codeia as long as a tolerance for it remains. Should, despite this, no benefit accrue, one may entertain the conviction that the remedy will here remain without effect, a conviction that will be the sadder, because there is no other remedy which will then be of benefit, and that might be employed to check or cure the disease. The physiological action of codeia in diabetes mellitus cannot be positively stated. But it is highly probable that it checks any increase in the production of sugar in the human economy through a calming of the glycogenic power, aided by the nervous system. Even if codeia does not cure all diabetes, to whom it is given, it still cures many, and almost every one is improved by it.

Salicylate of Mercury in Syphilis (*Journal de Médicine*).—Silva Aranjo, of Rio Janeiro, is the first who has employed successfully this new mercurial combination, obtained in 1886, by precipitation from an aqueous solution of nitrate of mercury by means of an alcoholic solution of salicylate of potassium. The precipitate appears under the form of an amorphous white powder, void of taste and odour.

The following therapeutic results have been obtained by Szadek:

1. In *Blenorrhagia*, the salicylate of mercury has no influence upon the duration of the morbid process. It exercises an undoubted antiseptic action, but it is inferior to the sublimate solutions:

℞.—Salicylate of mercury ..... 0 gram. 10.
Distilled water .....250 ,,
Bicarbonate of soda..... 1 ,, to 1 gram. 30

For injection.

2. In *Syphilis*. In the primary and secondary specific affections (chancre and condylomata), Szadek has used a mixture of the salicylate of mercury with the subnitrate of bismuth or a pomade (0 gram. 10 to 0 gram. 50 of the salicylate to 30 of adeps præparatus), which is applied directly to the diseased parts. For internal administration, he prescribes:

℞.—Salicylate of mercury ..... 1 gram.
Excipient q. s.

To be divided into sixty pills, and three to six pills to be taken after meals.

In a dozen cases Szadek has also employed the following formula for intramuscular injections:

℞.—Salicylate of mercury ..... 0 gram. 20.
Mucil. of gum arabic ,..... 0 gram. 30.
Distilled water .....60 gram.

The number of injections was raised from six to sixteen, according to the disease, with intervals of two and three days between them. There was none, or at least very little, local reaction (pain, inflammation, etc.) There were no indurations, abscesses, or general mercurial symptoms. Eight to ten injections ordinarily suffice to cause a disappearance of the syphilitic symptoms.

In conclusion, it may be stated from the observations of Szadek, that the salicylate of mercury is as efficacious, at least, as the other mercurial preparations now in use. It possesses the advantage over the latter of not producing any symptoms of local irritations or of general intoxication.

Collodion for the Teeth (*Bollettino Farmac.—Journal de Médicine*).—

℞.—Acetate of morphine .....0 gram. 05 centigr.
Essence of mint..... 4 drops.
Pure carbolic acid.....20 ,,
Collodion ..... q. s. ad. 4 grammes.

To be applied with cotton.

Naphthalin as an Antiseptic (*Journal de Médicine*).—Dr. Nager prefers this to the more dangerous arsenical and mercurial preparations. It may be employed in solid or liquid form. A first solution is made by dissolving over a water-bath forty parts of naphthalin in eighty parts of chloroform, and then adding one hundred parts of benzine, allowing the whole to be heated until it is a perfect solution. To use the naphthalin in the solid form, this first solution is mixed with vaseline, one part in ten; to use it as a fluid, two hundred grammes of the first solution is used to make a mixture, with one kilogramme of perfectly neutral fatty soap. To obtain the latter make a mixture of one kilogramme of fat soap with one litre of boiling water, and add ten to twenty grammes of oleic acid until there is a neutral reaction.

Condurango (*Journal de Médicine*).—Since the use of this drug in the treatment of the late German Emperor, it has received considerable notoriety. According to Wyss, it is par excellence a tonic and stimulant of the gastric mucous membrane. It is prescribed as a decoction or in the form of a wine, both of which are undesirable preparations; hence, the author uses a concentrated fluid extract in doses of ten to twenty drops in half a glass of water an hour before meals.

Paraphenacetin (*Le Progrès Médical*).—In a communication to the Société de Thérapeutique, Dujardin-Beaumetz stated that paraphenacetin does not produce cyanosis and eruptions like antipyrin and acetanilid. It can be given in doses of two or three grammes without danger of intoxication, which is due probably to the fact of its solubility. Antipyrin should be administered especially for migraine of the congestive type, acetanilid for neuritis and the fulminating pains of locomotor ataxia, and paraphenacetin for vague, less localized neuralgic pains. In rheumatism the salicylate of soda is always the best preparation to employ; while the preceding preparations should be remembered as excellent analgesics but as poor antipyretics under these circumstances.

VI.—DISEASES OF THE SKIN.

On Pastes. Ueber Pastern. H. Gruendler (*Monatshefte für praktische Dermatologie*, No. 20, 1888).—The object of the pastes is a double one, viz. :—(1) The absorption of the secretions and excretions of the skin ; (2) the subsequent deposition of a powdery residue, which fixes the medicament on to the skin. Greundler experimented with various powders in order to determine which fulfilled these conditions most satisfactorily. Of the mineral powders he selected Kieselgur (a silicious sand composed largely of foraminiferous remains), talc (French chalk), bolus creta (kaolin), calcaria carbonica and zinc oxide ; of the vegetable powders ; starch, lycopodium and coffee ; and investigated their power of absorbing oil and water. The most absorptive was found to be magnesia carbonica, which takes up 5.5 times it weight of water, 7-5 times its weight of oil. The second best is Kieselgur, which takes up 3.4 times its weight of liquid. Then come kaolin, zinc oxide, and starch. Lycopodium is absolutely useless, since only under quite exceptional circumstances will it absorb any water at all. In spite of its power of imhibition, magnesia carbonica is of no use for pastes, since it produces merely a sticky mass and not a proper paste.

Jackson (G. T.) on Treatment of Sycosis Parasitica (*Med. Analectic*).—If the beard is not shaven, first wash with an antiseptic soap and apply night and morning :

℞	Ung. simp.	20.	parts.
	Resorcin	2.	,,
	Hydrarg. bichlor	0.05	part.

m

If the beard is shaven, a zinc paste, viz. :

℞	Ung. zinc. benzoat	90	parts.
	Terræ siliceæ	10	,,

m

may be substituted for the ung. simp. in the above prescription.

If the disease is very superficial it may be sufficient to touch the part with sublimate or resorcin pencil, or use a spray of :

℞	Resorcin	5.	parts.
	Hydrarg bichlor	0.05	part.
	Aq. Cologniensis,		
	Spiritus āā	50.	parts.
	Ol. ricini	1.	part.

m

When the disease is deeper and nodes have formed, the following plaster mass should be applied and bound down :

℞	Empl. hydrarg	10	parts.
	Ac. carbolici	10	,,
	Sublimate	1	part.

m

Epilation should be practised if pustulation has occurred, but not otherwise.—

Reynolds (H. J.) on a New Method of Treating Vegetable Parasitic Diseases of the Skin (*ibid*). —The method is by the use of electricity, and the mode of application is as follows : The surface should be cleansed of crusts, scales, and sebaceous matter. Saturate the sponge of the positive electrode with some parasiticide lotion, and place it upon the part to be treated. Place the negative electrode saturated with water on some point near by. The electrode should remain on each place several minutes, but the whole sitting should not be over fifteen minutes each day. The best parasiticide is a one per cent. solution of bichloride of mercury. The current used should be the galvanic, and as strong as can be comfortably borne by the patient. Usually a current produced by 5 or 10 cells will suffice.

Corbett (W. T.) Skin Diseases due to Defective Alimentation (*ibid*).—In common with other organs the corium requires a plentiful supply of oxygenated blood, but an additional amount is called for to supply the appendages of the skin, the proper nourishment of which is essential for the healthy condition of the skin as a whole. There is no doubt that defective alimentation is a potent factor in cutaneous pathology. In infancy it appears most frequently in eczema, and later on in urticaria and erythema. Eczema in infants often appears as the result of too early weaning when the child is fed with a little of everything. That skin diseases are the frequent result of irritation of the gastro-intestinal tract is well known, and this is frequently the result of defective alimentation. The last words of England's best known dermatologist, Sir Erasmus Wilson, in an address before the Medical Society of London, were : "Well, our first six patients are adults, say between forty and sixty years of age ; some have eczema, moist and dry, recent and chronic some erythema, some gutta rosea, and some lichen. We inquire into the functions of digestion and assimilation ; in the majority we find symptoms of gastric disorder, nausea, loss of appetite, flatulence, distention, constipation—all more or less confirmed. Our pen flies to the paper ; we are about to prescribe ; and for what ?—for indigestion and malassimilation. But our patient consults us for cutaneous disease, not for his stomach or liver or digestive organs, with which he finds no fault, and which he is not aware of being in a state of disorder ; while we, on the other hand, know the assimilative organs to be the cause of irritation, and if they be restored to their healthy function all the cutaneous symptoms will subside and disappear. Undoubtedly, when the *force majeure* has been dealt with, we shall advise our patient as to some local treatment, an ointment, a powder, or a lotion for the immediate relief of the skin ; but, practically, we treat the cutaneous affection as if it were altogether secondary in importance ; neither need we care to inquire too minutely whether the anatomical lesion is a hyperæmia, a papule, a vesicle, a discharge, or a state of desquamation. And if we be in want of a name to include the cases of this description, we might adopt the word assimilation, and consider this as an *assimilative group* of diseases."

Treatment of Carbuncles.—Prof. Verneuil of Paris recommends the steam carbolized spray frequently used. The strength used is 2 per cent. and applied for twenty minutes three or four times a day. The force of the spray he regulates by the feelings of the patient and is directed directly against the carbuncle or protected by a thin layer of muslin. Benzine when applied early and frequently to carbuncles will often check their development, and will relieve the pain and tenderness, but it should not be used over 2 or 3 minutes at a time. Rhigoline may be used instead of benzene, as its action is more immediate and lasting in its effects, and it can be used as a spray to produce local anæsthesia if an operation is required.

The Spirit of the Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, Tuesday, November 27th (Sir Edward Sieveking, M.D., in the chair). **The Etiology of Puerperal Fever.**—Dr. W. R. SMITH read a paper on this subject. The inquiry in connection with this subject was carried out at the Brown Institute at the request of the committee. Blood was obtained from the heart of a patient who had died of puerperal fever, and cultivations made on gelatine in the ordinary way. In the course of two or three days numerous colonies were present, all clearly of the same origin. This organism was isolated, and its growth carefully noted in various media—as gelatine, milk broth. It was found microscopically to be a micrococcus. Mice inoculated with it died in a few days. Blood taken from the finger of a woman suffering from puerperal fever, and cultivations made upon the surface, and in the depth of gelatine, in the usual way, numerous colonies appeared, and in every respect resembled those of the previous patient. The following conclusions were drawn from these experiments : (1) That this organism occurred in the blood of persons affected with puerperal septicæmia in considerable numbers in the form of streptococci. (2) That, culturally, differences of a marked character distinguished it from other streptococci. (3) That its actions upon rabbits and mice were distinct and definite. (4) That it could be distinctly distinguished from the erysipelas streptococcus of Fehllisen, and from the streptococcus pyogenes of Rosenbach.—Dr. QUAIN remarked that he did not think he could have been mistaken in proposing, at the last meeting of the society, that this very interesting paper should be postponed till there was full time for discussing it. The origin of the paper had been from a very generous offer of the Hon. Rollo Russell of £100 for the special investigation of the disease at the Brown Institute. The result had proved eminently satisfactory.—D. W. O. PRIESTLEY considered the paper and the discussion important. Some ten or twelve years ago, when a considerable discussion took place at the Obstetrical Society, under his presidency, the subject was more confused, and he hoped some further clue might be obtained by the microscope. He had himself suggested the importance of the bacteria in the matter. M. Pasteur has, eight years ago, also made some investigations into the blood of patients with puerperal fever. Though Dr. Smith had pointed out the difference between erysipelas and puerperal fever, yet he should himself feel it a most dangerous thing to go from a case of erysipelas to a lying-in-chamber.—Dr. BARNES thought that in spite of what had been done we were not far advanced in our knowledge of puerperal fever.—Dr. HERMAN felt Dr. Smith's paper deficient in not offering any answer to the questions as to whether all puerperal fever was caused by germs. In his opinion it was all caused from germs without noticing the great improvement there had been since the use of antiseptics. It has

been well known that if scarlet fever had been introduced into a lying-in-ward, scarlet fever and that alone was produced.—Dr. J. H. WALTERS said he had come up from the country for the discussion, and had been disappointed to find it so bacteriological. He agreed with Dr. Herman and as to autogenic puerperal fever he was not a little sceptical. He and his partners had not found it in cases of small supplemental placental large clots in the uterus, etc., where it might have been expected. He regarded insanitary dwelling houses as an important cause.—Drs. A. Money, William Duncan Routh, also took part in the discussion.

* * * *

BRITISH GYNÆCOLOGICAL SOCIETY, November 11th (Arthur Edis, M.D., president). **Fibroid Tumours undergoing Calcareous Changes.**—Dr. FANCOURT BARNES exhibited a tumour, partly calcified, he had removed from a young woman, æt. twenty-three. The tumour appeared to be growing from the omentum, and had no connection with the uterus or pelvic organs. It was closely adherent to the intestines. At the bottom of the pelvis a mass of chalky deposit could be seen and felt through a layer of peritoneum.—The PRESIDENT said he had never seen a similar case.—Dr. GRANVILLE BANTOCK exhibited the uterine appendages which had been removed from a married lady suffering from salpingitis, who had one child ten years before. The case was one of pyosalpnix, but the general health was bad, and the urine contained a large amount of albumen. He tried rest and treatment, and she seemed to improve, but the symptoms returned in a few days as bad as ever, necessitating operation. The patient made a good recovery.

Sarcoma of the Breast.—Dr. F. PURCELL exhibited a tumour, 5¾lbs. in weight, which he had removed from a woman, æt. forty-three. It was first noticed four years previously, on the seat of a small abscess. The disease was localised in the breast, the axilla being quite clear, and the arm perfectly free. The patient made a good recovery.—Mr. SPANTON said that sarcoma of the breast was rare, and among the whole of the cases in the North Stafford Infirmary did not number more than one in thirty or forty.

* * * *

MEDICAL SOCIETY OF LONDON, November 25th, 1888 (Sir William MacCormac, F.R.C.S., president, in the chair). **Case of Gôitre.**—Dr. GEORGE STOKER showed a man who had come under his care in April, 1888, with a large central well-defined gôitre, the size of a small hen's egg. Iodide of potassium internally, and irritants externally, were given without any effect. In June he had symptoms of chronic hypertrophic rhinitis, which caused much inconvenience. The middle turbinated bodies were much thickened, and this was treated by galvano-cautery. The cauterisation was continued up to a fortnight of the present time, and the gôitre had now completely disappeared.

Cases of Partial removal of Gôitre.—Mr. LENNOX BROWNE showed three young male patients, from two of whom he had removed the isthmus of the thyroid; from the other the isthmus and right lobe weighing 7¾ ounces, and in each instance with the result of giving complete relief to distressing dyspnœa. He was disposed to think that the danger of myxœdema after entire removal has been exaggerated, but seeing that it did not exist, he thought it better to do only a partial operation. He had now removed either the isthmus, or the isthmus and cone, in ten cases, and in all cases with a comparatively good result. The President, Dr. Hadden, Dr. Bernard Pitts, all joined in the discussion.

Palio-Myelitis after Injury.—Mr. BEEVOR showed this case. A boy of twelve fell violently on his elbow last August. His arm was put in splints for a fracture of the humerus. A month later, when the splints were removed, certain muscles were found to be paralysed. There was no anæsthesia.—Dr. SIDNEY PHILLIPS asked whether the apparatus might not have caused the paralysis by pressure.

Case of Erythema Gangrenosum,—Dr. CAMPBELL showed a young married woman who had been the subject of syphilis, and who, some time after, had come to him with erythematous patches on the forehead and chin, and later between the nates and on the vulva, imperfectly vesiculated, and giving place to shallow superficial ulcers. He called the case one of erythema gangrenosum for want of a better designation.—Dr. CROCKER suggested that the ulcers might be self-produced.—Dr. CAMPBELL denied that this was possible, given the situation of the eruptions.

Neuro-Muscular Irritability.—Dr. HADDEN exhibited this patient. The man originally had a condition of spasmodic paraplegia, which was evidently not of spinal origin. The rigidity of the legs disappeared under rest and treatment, but could be brought about afterwards by percussing the muscles. The man was an athlete, so it was possible his condition was due to over-exertion. The condition resembled in some points the disease known as Thompson's Disease.—Dr. MONEY said he had noticed somewhat analogous contractions in cases of chorea after typhoid fever.—Dr. HADDEN was disposed to ascribe the symptoms noticed in this man to irritation produced by fatigue.

* * * *

CLINICAL SOCIETY OF LONDON, November 23rd (W. H. Broadbent, M.D., president, in the chair). **Purulent Pericarditis Treated by Aspiration and Drainage.**—Dr. RICHARDSON brought this case before the Society. A boy, aged ten, had symptoms which both Drs. Harris and Woad, of Norwood, interpreted as pyæmic. A large gluteal abscess was followed by signs of pleural effusion and œdema of the face and chest. The position of the heart was almost indiscernible amidst the dulness which involved the left pleural and precardial regions. On the 18th the pleura was aspirated, and thirty-seven ounces of serum drawn off. The operation was repeated on the 23rd, with the removal of thirty-two ounces. The operation had to be repeated on the 25th and 28th, so rapid was the re-accumulation and so great the dulness. On the 30th the futility of dealing with the pleura having become apparent, the pericardium was aspirated by Mr. Rouse, and one ounce of creamy pus withdrawn. The aspirator was repeated with more success on July 8th, and on the 15th. The place selected for puncture was on the right side, close to the edge of the sternum in the fifth inter-space. The heart, before each of these operations, had been drawn to the left by a preceding evacuation of the pleura. Recovery took place, after some temporary drawbacks, by the middle of September. There was no remnant of the pericardial puncture, except a small cicatrix.

* * * *

BRISTOL MEDICO-CHIRURGICAL SOCIETY (R. Shingleton Smith, M.D., president, in the chair). **Cancer of Liver in a Cat.**—Dr. HARRISON exhibited the liver of a Civet cat, with large, soft growths in its substance resembling encephaloid cancer.

The Field of Vision.—Dr. RICHARDSON CROSS read a paper on the field of vision, normal and abnormal. He pointed out that the *macula lutea* was the most highly organised part of the retina, and the most elaborately supplied with blood, hence inflammations and hæmorrhages were more liable to occur there than anywhere else.

Naphthol in Typhoid.—Dr. MITCHELL CLARKE read a paper on the value of the above in typhoid fever. He suggested that the so-called bacillus typhosus was the cause of disease, so that something should be introduced into the alimentary canal to prevent the growth. Naphthol fulfilled these conditions, and appeared to have shortened the duration of the fever.

* * * *

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY, Thursday, November 28th (J. W. Martin, M.D., president, in the chair). **Graves' Disease.**—Dr. PORTER showed the patients—one a young married woman, aged twenty-one, suffering from exophthalmic goître. The goître first made its appearance eight years ago. The symptoms were nervousness, palpitation, throbbing, anæmic bruits over pulmonary artery and at the apex, etc. She had not menstruated for three months.

Aortic Stenosis.—The second case was one of aortic stenosis in a man, aged fifty-five. There was history of an illness some years previously, but no rheumatic history. The pulse was small, the general symptoms were syncopic attacks and vertigo, the patient sometimes falling, but never fainting quite away.

* * * *

GLASGOW SOUTHERN MEDICAL SOCIETY, Thursday, December 6th (T. F. Gilmour, L.R.C.P. Ed., in the chair). **Historical Sketch of the Society, by John Dougall, M.D.**—The CHAIRMAN announced that copies of the History of the Society, which Dr. Dougall had been commissioned to prepare, were now ready for distribution among the members. The little book contains a photograph of the late Dr. James Stewart, the first president, and a copy of the quaint, original seal of the Society. The sketch is mainly compiled from the minute books, which record the chief items of the transactions of the Society since its origin in the year 1844. Much interesting information is given regarding the society's origin, infancy, growth, and work, affording many glimpses of the state of medicine as practised in Glasgow nearly half-a-century ago. The extracts from the record by the original secretary, Dr. Leech, who usually signed himself "Hirudo Officinalis," show that he was a man of wit and humour, and did not confine himself to strictly business minutes. Dr. Dougall gives notices of the more prominent past members, and makes reference to the principal papers read on medical subjects, and also to the part which the Society has on various occasions played in relation to important questions affecting the profession and the

public. One amusing paragraph in the booklet consists of a description in verse, by one of the members of the society, and is entitled "A Medical Holiday." A list of the present office-bearers and members is appended, the total number on the roll being 156.

Medical Characters in Fiction.—The continuation of the President's paper on "William Smellie" having been unavoidably postponed, the Secretary, Dr. James Erskine, M.A., read a paper on "Medical Characters in Fiction" as an introduction to a conversation on the subject. As representing the extent to which the treatment by leeching was carried in olden times, Dr. Sangrado in "Gil Blas" was selected. The medicals in Scott's works were passed under review, especially Dr. Quackleben in "St. Ronan's Well," and reference was made to the two doctors in Thackeray's writings—viz., the admirable and kind-hearted Dr. Goodenough, and the pretentious fraud Dr. Firmin. Mr. Lydgate, in George Eliot's "Middlemarch," was noted as a man whose noble and unselfish nature was repressed and spoiled by a wife, who cared only for material prosperity and luxury. R. L. Stevenson's "Strange Case of Dr. Jekyll and Mr. Hyde" was graphically represented, and the moral of the story considered. The medical characters of Shakespeare's "Macbeth," "Cymbeline," "King Lear," etc., received special comment. Sterne's "Tristram Shandy," and Smollett's "Roderick Random" were referred to, as also Trollope's "Doctor Thorne." Dr. Day in Miss Yonge's "Daisy Chain," Mr. Woodcourt, poor Jo's friend, in Dicken's "Bleak House," and the medical personages in Charles Reade's "Hard Cash," Wilkie Collins' "Heart and Science," Mrs. Henry Wood's "Oswald Cray," James Payn's "Thicker than Water," Hawthorne's "Mosses from an old Manse," and Cable's "Dr. Sevier." Rebecca, in Scott's "Ivanhoe" was regarded as the prototype of the modern medical woman, and "Dr. Breen's Practice," by W. D. Howell's, was taken as an illustration of the lady practitioner of the present day. The nurses in fiction were discussed. Dicken's Mrs. Gamp and Mrs. Harris, in "Martin Chuzzlewit," were looked upon as exaggerated caricatures of the evils of nursing as conducted in bygone times. The Little Sister in Thackerary's "Philip" was considered as a splendid type of the modern nurse, and the two nurses in "An Open Verdict," by Miss Braddon, and Sabina Zambra in William Black's novel of that name, were mentioned as examples of the kind of women introduced into the modern novels for the purpose of carrying out the love-plot of the story.

Surgical Aids and Appliances.

115.—A BENCH FOR OPERATING ON THE EYES OF CHILDREN.

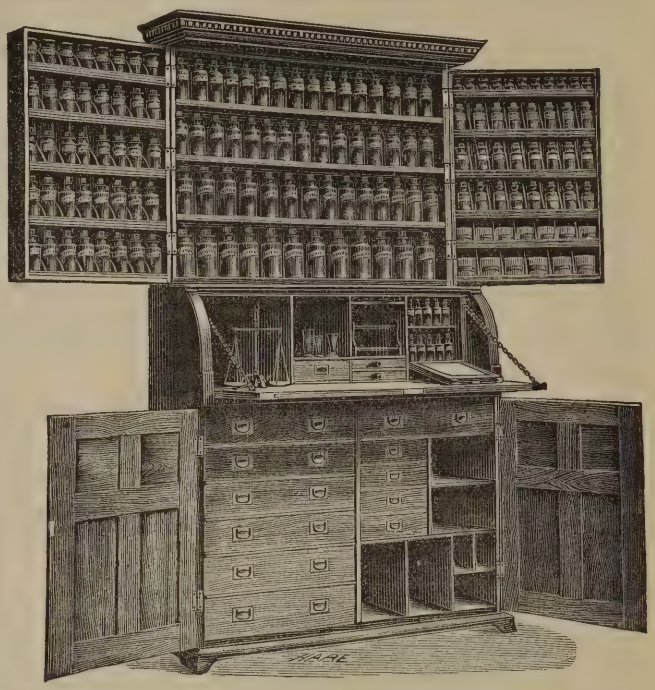
By TEMPEST ANDERSON, M.D.,

OPHTHALMIC SURGEON YORK COUNTY HOSPITAL.

THIS contrivance, which was exhibited at the recent meeting of the Yorkshire Branch of the British Medical Association, consists of a bench of the ordinary height of a chair, and with a top 4ft. 6in. long by 1ft. wide. On either side near the middle of the bench, part of the seat is cut away and the framing carried under the middle so as to allow the operator's knees to come nearly together. He sits astride of the bench, and the child is laid on its back on the other end so that its head rests between his knees on a towel laid over them. The mother or nurse controls the child's arms. The movements of the legs are immaterial, in which respect this bench has a great advantage over the ordinary method of laying the child over the nurse's knees. A strong child of two or three years old can by a sudden kick shake a nurse, and give a jerk to its head held between the kness, while on this bench it is perfectly steady, and many ordinary cases such as tinea tarsi, photophobia, or small abscesses of the eyelids or face, which would otherwise require chloroform for their proper examination or treatment, can be effectively dealt with. When not in use the bench is a useful piece of furniture in the surgery or waiting room. Mr. Baxter, joiner, 68a, Lowther-street, York, has made several such for the author and his friends.

116.—A PRIZE DISPENSING CABINET.

IN response to the offer in our columns of a prize of £5 5s. 0d., several designs were sent in, from which one was selected, and after some detailed alteration, adopted as Richardson's Prize Cabinet. The chief conditions of the prize were that the cabinet should be useful, compact, and elegant in appearance, and as may be seen by referring to the accompaning drawing, all these conditions have been fulfilled. The cabinet as manufactured forms a handsome piece of furniture, and is fit for any consulting room. It is made of the best polished pitch-pine, and is divided into three compartments. The base, enclosed by folding doors, contains seven large and four small drawers, and seven divisions for dispensing bottles, mortars, etc. The middle division (the front of which lets down and forms a most convenient dispensing counter), has space for 12-inch pedestal scales, graduated measures, ointment slab, test tubes, compressed tablets, and other small bottles, and one drawer for instruments,



etc., three drawers for labels, and a hinged sloping desk. The top portion of cabinet is fitted with shelves made to carry twelve 16oz., fourteen 12oz., and thirty 8oz. bottles. The inside of the folding doors is also divided into compartments for sixteen 8oz., forty 4oz. bottles, eighteen pill bottles, six 8oz. ointment pots, and seven 4oz. ditto. The size of this cabinet is 7 feet 3 inches high, and 4 feet 2 inches wide at the base. The front is highly finished, and is divided into 17 moulded panels, and has a 3½ inch moulded and dentilled cornice. The cabinet may be inspected at 6, Great Russell-street, Bloomsbury, and may be obtained furnished or unfurnished on terms which may be ascertained from John Richardson & Co., 10, Friar-lane, Leicester.

Medical Miscellanea.

THE subject of our next illustration will be Lionel Beale, M.D., F.R.S.

* * * *

There will be a new edition of the "United States Pharmacopœia" in 1890.

* * * *

The Italian Society of Hygiene will hold its next Congress at Padua in 1890.

* * * *

The French Minister has presented a sum of 8,000 francs (£320) to the Academy of Medicine, for the encouragement of animal vaccination.

* * * *

Surgeon-Major G. Waters, L.R.C.S., L.R.C.P., has been appointed first physician, and Surgeon R. Manser, M.R.C.S., L.S.A., second physician to the Jamsetjie Jejeeboy Hospital.

* * * *

Dr. J. B. Hamilton, Surgeon-General of the Marine Hospital Service, and late Secretary-General of the Ninth International Medical Congress, has been chosen to fill the place of Dr. Nathan Davis, who has resigned the editorship of the *Journal of the American Medical Association.*

The foundation stone of Hereford new Victoria Ear and Eye Hospital, which is to be built in commemoration of the Queen's Jubilee, at a cost of £2,500, was laid on December 6th by the Countess of Chesterfield.

* * * *

Dr. W. H. Torbock, of Polruan, Cornwall, has received for the second time the Government grant for successful vaccination in the fourth and fifth districts of the Liskeard Union.

* * * *

The public appeal on behalf of Guy's Hospital has resulted in a generous response. Already £97,000 has been subscribed; some beds have been re-opened, and there is every prospect that the governors will find themselves able to open the 600 beds which the hospital contains.

* * * *

At the congress of the advocates of cremation, recently held in Vienna, it was stated that there are throughout the world fifty crematories, half of which are in the United States, twenty in Italy, and one each in Germany (Gotha), England, France, and Switzerland.

* * * *

A most successful meeting of those interested in the Royal Albert Asylum was held at Halifax on December 18th, under the presidency of the Marquis of Ripon, and the objects of this charity were ably advocated by several speakers.

* * * *

A lad named Arthur Micklefield, aged seven years, was bitten by a mad dog in London. He was being taken to Paris in order to be placed under the treatment of M. Pasteur, when he died in the train, between Dieppe and Paris.

* * * *

The cause of ill temper has been discovered by a dress reform lecturer, who does not consider it an evidence of bad disposition. She says it is caused by bodily discomfort, improper dressing, etc., and that wives would all be sweet-tempered if they took plenty of exercise, and ate their food and digested it well.

* * * *

At the anniversary meeting of the Royal Society, on St. Andrew's Day, the Copley Medal was presented to Professor Huxley, F.R.S., F.R.C.S., for his investigations on the morphology and histology of vertebrate and invertebrate animals. The Royal Medal was given to Baron von Müller for his investigations on the flora of Australia.

* * * *

We hear that another medical novel is in the press, entitled, "Queen Anne's Hospital." It is by Dr. Schofield, and is written on teetotal principles, and is a kind of answer to another novel which brought sensational charges against hospital surgeons, and their method of treating ward patients.

* * * *

We regret to have to announce the death of Denis Charles O'Connor, LL.D. Camb., A.B., M.D. Dublin, one of the most skilful of the medical practitioners of Cork. Dr. O'Connor was appointed, on the opening of the Queen's College, Cork, professor of the practice of medicine, and during the meeting of the British Medical Association in that city, in 1879, was chosen president of the association. He will be very much regretted by all who knew him.

* * * *

We regret to have to record the death of Dr. Henry Sands, one of the leading surgeons of New York. Dr. Sands was a member of the New York Academy of Medicine, the County Medical Society, the Physicians' Mutual Aid Association, the Society for the Relief of Widows and Orphans of Medical Men, and of the Medical and Surgical Society. He was also connected with the New York Philarmonic Society.

* * * *

A very good kind of doctor is described in an able novel, entitled, "A Bitter Repentance," by Lady Virginia Sandars. The doctor (by name Tremaine) is finely drawn, and is a very noble specimen, albeit not in the flesh. The following paragraph is worth quoting: "Sir Godfrey Tremaine, I congratulate you," exclaimed Conway. "Brewers and gin distillers having realised their millions, and aided in destroying the moral and physical well-being of their fellow creatures, receive peerages in recognition of wealth so meritoriously gained. Physicians who are called upon to prolong life, often at the expense of their own, may not hope for higher distinction than a baronetcy."

The well-known London surgeon, Mr. Davy, F.R.C.S., has entered on a new field. He has written one play entitled Lesbia, which has been produced at the Gaiety, and now we are informed he has another in hand for Mrs. Langtry.

* * * *

A new Surgical Aid Society has been formed at Newcastle-on-Tyne, with the object of supplying medical appliances for the deserving poor. A resolution was moved by Dr. Philipson; a committee elected, which was to consist of the senior physicians and surgeons of the town. There can be no better system, and the institution will be thoroughly unsectarian.

* * * *

Apropos of the application of Sir W. Roscoe for a grant in aid of the Pasteur Institute, owing to the fact that about 180 English people had applied for the cure, the following old story is worth reviving:—

First boy: "Didn't Joe Stevens have a slice of luck just now."

Second boy: "Gor! what's up?"

First boy: "He's been bit by a dawg, and now's over in Parry, 'aving a 'owling lark."

Second boy: "Just his blessed luck."

What about *the thousands* who have been bitten in England by dogs, and who have applied to our charities. The Government should first subsidise the London hospitals.

* * * *

We have taken the following from *Keene's Bath Journal*, December 15th, 1888:—In an unmistakable manner Dr. Freeman has sounded the key-note of his mayoralty; the challenge has gone out, and henceforth the baths and their advancement will be his particular care. This is no more than was anticipated when he first consented to accept the dignity of chief magistrate of the city, but it could not then be foreseen that at so early a stage he would enter actively upon his campaign. Viewed in this light, the banquet given by the mayor on Monday was no ordinary affair. Dr. Freeman turned the opportunity to the direct good of the city. The worth of the gathering consisted in the assemblage of so many medical men, not only from the city, but from various parts of the country, and from the metropolis. The prosperity of Bath is in the hands of the profession. Fortune may do much; nature also has given great beauty to the city's surroundings; yet neither the patronage of fashion nor the panegyrics of ardent tourists would be so beneficial or lasting as the persistent upholding of the virtues of the waters of Bath by physicians at home and abroad. The chief speaker of the evening was Dr. Lennox Browne, once a fellow student with the mayor. His words had in them the true ring of conviction when he asserted that no other place "can offer the same aggregate of advantages to the invalid as Bath." Commenting on the rise in the prosperity of the baths, which he dates from the meeting of the British Medical Association in Bath ten years ago, under the presidency of the late Dr. Falconer, Dr. Browne finds that their income has increased from 300 to 400 per cent., and he hopes to see a still more substantial advance in the future. If the spirit which appears to actuate Dr. Browne diffuses itself amongst his professional brethren, there will be no fear of the result. The mayor leads the van in the new crusade with energy and determination, nor will he lack influential followers. Public attention must be rivetted to the virtues of the thermal waters.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

THE EARLY SYMPTOMS OF CHRONIC PLUMBISM.

A PERSONAL EXPERIENCE.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Having recently suffered from a very vague attack of chronic lead-poisoning, which for long baffled the diagnostic powers of eminent members of our profession, my attention has been particularly drawn to the subject, and the conclusion is forced upon me that such cases are by no means rare. In 1886-7 several persons in Sheffield were attacked by vague symptoms, which for a long time could not be accounted for, but eventually they proved to be cases of chronic lead poisoning from drinking water. Dr. Thomas described some of these cases in the *British Medical Journal*, and in his subsequent remarks he makes this important statement: "I believe in the past that I have seen scores of cases of plumbism, which I have never recognised, simply because I was not on the look out for them, and that probably is the experience of hundreds of other medical men." I might quote many other authorities to prove the correctness of my conviction that many unrecognised cases occur, where the usual pronounced symptoms are absent, and I think that these cases ought to be made out early, for though the initial symptoms are extremely vague and indistinct, with great care in their investigation they may usually be distinguished.

These symptoms have been frequently described more or less fully in various text-books and medical journals, but my personal painful experience, and my observation of these symptoms in various members of my household who have unconsciously taken drinking water impregnated with lead for a considerable period, may be of some interest to your readers, and may attract renewed attention to a very suitable and, I believe, very general cause of chronic ill-health. The effects of chronic lead poisoning are at first so obscure, so slow, and so insidious, that they are readily mistaken for other debilitating diseases.

Case 1.—In March, 1884, I removed from a neighbouring house, which was not supplied with a hot water service, and which had no leaden pipes for the conveyance of water, to my present residence, which is fully fitted throughout with a hot water serviee, supplying the kitchens and bath-room, and which contains both leaden pipes and a leaden cistern. The cold water supply is distinct; it comes direct from the main in iron pipes, and has no contact with lead. Previous to my change of residence my health was uniformly good, and I suffered from no gastric or abdominal disturbances; but afterwards, a gradual and almost imperceptible change took place. The following symptoms of chronic ill-health appeared, more or less in the order stated below:

1. Vague symptoms of *dyspepsia*—slight headache, absence of mind, forgetfulness, slight mental depression, flatulence, abdominal distension and uneasiness.

2. Chronic and persistent *constipation*, each year becoming less amenable to treatment. In 1886 severe straining induced prolapsus ani, and enemata became habitually necessary. Hæmorrhage from the bowels occurred occasionally. Careful examination of the abdomen externally, and the rectum digitally, at this period detected no diseased condition.

3. *Vomiting* occurred frequently and suddenly, without previous warning. Complete relief followed evacuation of the stomach.

4. The tongue became *constantly furred*, particularly in the morning, and a sweetish astringent taste occurred.

5. *Headache* became more marked, accompanied by melancholia, depression of spirits, and an indefinable sense of impending evil.

6. A tendency to sleep during the day, especially after the midday meal, accompanied by muscular debility, a feeling of languor, and disinclination for exertion, also a sense of chilliness, and a shrinking from exposure to cold.

7. *Vertigo* occurred suddenly and frequently, and passed off after a few seconds.

8. A *marked cachexia* gradually developed, and became very apparent towards the end of 1887, shown by gradually increasing emaciation, hollowness of the cheeks, sharpness of definition of the features, a sallow skin, muddy conjunctiva, fetid breath disagreeable to friends, but not perceived by myself. In January, 1888, I suffered from a severe chill, with nasal catarrh and sore throat. Two days after this occurred, sickness and diarrhœa set in, with severe tenesmus, followed in twenty-four hours by intense tormina, occurring in paroxysms in the region of the transverse colon and sigmoid flexure. This was probably

9. *Lead colic*, and it terminated in acute enteritis of the sigmoid flexure, which kept me an invalid for many weeks.

The above symptoms gradually disappeared, after the discovery of the cause of the chronic ill-health and suitable treatment, directed (1) to the relief of the acute symptoms, (2) to the elimination of the poison, and (3) to the restoration of the general health; but a constant aching, and feeling of stiffness and soreness remained in the abdomen, though the constipation is no longer present.

Case 2.—Maiden lady, æt. fifty-nine, stout, previously healthy, gradually fell with ill-health, and showed a marked cachexia, which was at first attributed to derangement of the liver. She complained of increasing inability to walk, had a tendency to stumble, giddiness, increasing insomnia, palpitation, cardiac uneasiness and oppression. The pulse was slow (sixty), hard, intermittent, no cardiac murmur. Abdominal uneasiness and gripings were present, constipation, and slight albuminuria.

Case 3.—Married lady, æt. thirty-four, previously healthy, suffered irregularly for three years from morning sickness, immediately after breakfast, and occasionally during the day. She felt well immediately after the rejection of the food. Severe syncope, without unconsciousness, occurred almost daily, and invariably about two hours after breakfast. The pulse became uniformly slow and weak, rarely exceeding fifty. The breath was frequently fetid, and there was abdominal uneasiness, but no albuminuria nor constipation. Anæmia was present.

Case 4.—A boy born in the house in 1884 suffered from habitual constipation after he was weaned, except when he was taken from home, when the bowels became regular. He had sudden attacks of syncope (without unconsciousness), with deadly pallor and fetid breath, generally terminating in sickness, and cramp in his legs often occurred in sleep.

Case 5.—Single lady, æt. thirty-four, suffered from chronic constipation, constant headaches, and amenorrhœa; finally, from melancholia of a severe type, amounting to slight mental aberration.

Case 6.—The cook, a young woman æt. twenty-eight, after chronic dyspepsia, constipation, and a slightly-marked cachectic appearance, suddenly was attacked by colic.

In each of the above cases the sufferers recovered under proper treatment, after the discovery of the lead poisoning, with the exception of case No. 5, where the improvement has been slow, and is not yet complete. The servants had been frequently told to use for drinking purposes the cold water, which was supplied direct from the main in iron pipes; but upon careful and searching investigation, it was ascertained that for the sake of convenience, and to save time, they had habitually used for breakfast, and for the child's food, the hot water which had remained in the lead pipes all night. This water was submitted to Professor Attfield for analysis, and showed the following result:

June 25th, 1888.	Hot water service contained $\frac{1}{100}$ grain, or 0.01 lead per imperial gallon.
June 25th, 1888.	Cold water service, no trace of lead.
July 3rd, 1888.	Hot water service contained between $\frac{1}{60}$ and $\frac{1}{100}$ grain, or 0.02 to 0.61 grain lead per gallon.
July 3rd, 1888.	Cold water, no trace of lead.

The water supply of this town is collected from hills of the silurian series. The gathering-ground is peaty, and the water, after heavy rains, is frequently, before filtration, of a brownish colour, throwing down a peaty deposit. It runs in iron pipes for a distance of seven miles (from the reservoir to the town). The following is the analysis of this water, made by the medical officer of health (results expressed in grains per imperial gallon):—

Total solid matters	7.0
Chlorine (as chlorides)	0.75
Hardness total	5.5
Free ammonia	0.02
Oxygen required to oxidise organic matter actually present	0.18
Nitrates, nitrites, and metallic impurities	0.0

And he remarks: "The water is quite free from all evidence of hurtful organic or other contamination; is remarkably soft, and well fitted for every domestic purpose." But it will readily be seen that it is well adapted for dissolving lead, on account of its softness and freedom from

the salts which, by precipitation upon leaden pipes, prevent further action upon the water. This solvent action may derive further aid if the water at any time contains a free acid, due to the oxidation of iron pyrites or to the decomposition of vegetable peat."

The amount of lead found by Professor Attfield in my hot-water service is certainly small, but probably the actual amount may vary considerably at different times ; a much stronger solution may be sometimes present. A very small quantity of lead in drinking water renders it injurious to health, and if only $\frac{1}{10}$ grain per gallon, or even one part per million, be found, it is stated on good authority that such water ought to be avoided for drinking purposes. In Huddersfield chronic plumbism has resulted from water containing from 0.04 to 0.84 grains per gallon, and in Leeds from a solution of $\frac{1}{20}$ grains per gallon. In the remarkable case of poisoning in the household of Louis Philippe, in Claremont, plumbism was produced in seven months by drinking water which, upon analysis, was found to contain not more than 0.0015, or even 0.0002 per cent. of lead.

When this poison is absorbed in very small amount decided symptoms may not follow for an indefinite period, on account of the power of the system to eliminate it by the urine, skin, mucous membrane, and the epithelium ; but if this action be checked by a sudden chill, or an ordinary cold, serious and unmistakable symptoms may suddenly appear.

It is not my intention to give an exhaustive list of the numerous and various sources of lead-poisoning, or to describe the symptoms of advanced cases rendered easily recognisable by the presence of colic, marked blue line on the gums, wrist drop, etc., or to enter upon the question of treatment, but briefly to attempt to enumerate and describe the earliest recognisable symptoms which, though vague, are so distinct as to lead to an early diagnosis if carefully studied. Impaired nutrition lies at the root of cases of incipient chronic plumbism.

Constipation is one of the earliest and most constant symptoms. Sometimes irregularity of the bowels first occurs, so that constipation and diarrhœa alternate. But as the case progresses, the costiveness becomes more constant and more obstinate. When ordinary purgatives fail to act lead-poisoning may often be suspected.

Abdominal uneasiness is an early symptom, and a very characteristic one. At first it occurs only after food, but gradually becomes more constant. A feeling of stiffness, aching, gnawing, or contraction, is an early symptom, and is succeeded at a rather later stage by gripings, a hot burning sensation, and occasional spasmodic attacks.

Pain in the back, of a grinding or dull aching kind, occurs.

Dyspepsia is always present a little later, shown by furred tongue, headache, flatulence, and by a peculiar kind of vomiting, which occurs suddenly, without any previous warning.

The saturnine cachexia becomes apparent, and is characterised by increasing emaciation, the face looking thin, the features drawn and sharply defined, the countenance sallow or yellowish (the icterus saturninus of Tanqueral), the breath is fetid, the conjunctiva muddy. Muscular weakness sets in, and a well-marked anæmia. Though this condition is apparent to his friends, the patient may himself feel well.

Melancholia, or depression of mind, with loss of memory and disinclination for exertion, appears, with a tendency to sleep during the day. Slight mental aberration may occur in some cases, leading to lunacy. Four cases are reported by Dr. Goodhart in the *British Medical Journal* for 1882.

Vertigo may occur in one case, *syncope* in another. These symptoms should give rise to suspicion at once in the absence of organic disease, especially if the pulse be slow (forty to sixty) and hard, or cardiac uneasiness or palpitation be present.

Slow pulse is frequent, apart from syncope.

Albuminuria also occurs, and *insomnia* is often attributed by the patient to cardiac discomfort.

Suppression of catamenia, and sometimes *abortion*, occur in women.

The *blue line* upon the gums is a valuable and conclusive indication of lead poisoning, if present, but it is generally absent in those who habitually brush the teeth.

Many months, or a year or two, may be required to produce the above symptoms in a decided form, the period varying with the amount of lead in solution and the susceptibility of the patient ; but when a number of the above symptoms occur, in the absence of all specific disease, the medical attendant ought to search carefully for lead, and not rest satisfied with an incomplete investigation.

Water contamination from leaden pipes or cisterns is by far the most usual source of chronic plumbism in its most insidious form. In the trades in which lead poisoning occurs the symptoms are usually so decided that the disease is readily diagnosed. Obscure cases have been traced to various sources of lead action—viz., to flour, where the millstones have been repaired with lead ; to the use of aërated waters from syphons which have been found to contain 0.0408 grains of lead per gallon ; to beer drawn from lead pipes, or to beer or wine from bottles containing shot ; to snuff packed in lead foil ; to badly-glazed crockery ; to tea containing oxide of lead (from its being packed in lead in China), etc., etc. It is well known that many of our large towns are supplied with a water capable of taking up lead, when allowed to lodge in the pipes for twenty-four hours in an appreciable quantity—for instance, Bradford, Halifax, Leeds, Manchester, and Sheffield—therefore chronic plumbism may have a wide influence in producing a chronic form of invalidism difficult to alleviate till its cause is understood.

I am, yours truly, "M.D. EDIN."

"ON THE EXTERNAL APPLICATION OF NITRATE OF SILVER IN ERYSIPELAS."

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Through the means of your highly-appreciated publication, please allow me to draw the attention of your numerous readers to the above-mentioned remedy in the treatment of erysipelas. Not that there is any originality on the part of your humble servant, for he has gratefully to acknowledge his obligations to his former colleague, Dr. James Allan, of Leeds, who was the first person to direct his attention to the silver solution as an external application in the treatment of this disease. At the same time (if my memory holds goods) I think Dr. Allan himself saw it highly recommended in some one or other of the medical journals. The same gentleman has recently read a paper on the subject before the Leeds Branch of the British Medical Association, but his remarks were not fully reported, neither did their seem to be much discussion upon the subject when brought before the members.

Having lately had an unusual number of these sort of cases under treatment, I have been more than ever struck with the remarkable usefulness following the external application of the silver solution ; also during the last seven years I have applied it in almost every case, and with the most gratifying success. I therefore desire to supplement Dr. Allan's experience with that of my own. It cannot be used very well in some cases. It is not advisable to employ it freely where there are any blisters, or where there may be any crushing. If possible it ought to be employed before that stage. The best and proper strength will be found to be gr. 20 arg. nit. to each ʒi. of sp. ether nit. If called to a case I generally run a little cotton wool gently over the surface of the skin, so as to remove any secretions that may be lying thereon. After pouring a little of the remedy into a wineglass, and having charged the camel-hair brush with some of it, I then give the affected parts a good coating by running the brush once or twice over the skin. In a short time the parts so painted will get brown and eventually quite dark. A fine uniform covering will be formed, and will be found much better than cotton wool, etc., as a protection from the air.

With steel internally and this application externally, it is often marvellous how quickly the patient will get better. I have such faith in its usefulness from past experience that I am generally enabled to confidently assure the sufferer that they will very soon be all right. There is also a grateful cooling feeling at the time of painting, and the burning sensation present in erysipelas (if nothing be done) is generally removed. I should very much like to hear the opinion of any of your readers who may have tried this treatment. Apologising for troubling you.—Yours truly, T. PICKTHORN THOMAS, M.B.

Half-Way House, Shrewsbury,
November 29th, 1888.

☞ We would direct attention to Higginbottom's treatise "On the use of Nitrate of Silver in the Cure of Inflammations, etc.," in Leeds Medical Library.—W, 47.

MEDICAL REFORM.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—It is perhaps useless to offer any criticism of the paper on the above subject, appearing in your Journal of December 1. Few fair-minded persons will read it without noting the ruling sentiment of it all, which pervades most of the effusions of this, and similar expositions of like "reformers"—viz., an intolerant jealousy of Scotch and Irish medical credentials to practise in England. But it is apparent that the writer of the article referred to is ignorant of certain facts in the case he takes up, and with the view of rectifying this, you will perhaps

permit me space to shew him that "in the legal profession there are several grades of superiority"—granted; but is it not a fact that at the present day these "several grades" are found to be a galling yoke of bondage instead of a benefit by the said profession. One thing is certain, that both in England and Scotland, organisations are on foot for the abolition of the system which is held by "reformers" in the legal profession to be irksome, and amid the general efficiency required throughout that profession, uncalled for. In scanning reports of meetings on the subject by legal men, we find the unicity and uniformity of our profession pointed by legal luminaries as a model of what the legal profession should be. The fact of English solicitors, etc., being limited to England, and Scotch to Scotland, is because the law is different; legal processes, terms, etc., are altogether different. It is clear this instance is quite out of the question in considering the question of medical practice. As regards the clergy, I need only say there is another great body where no such system prevails, and its traditions, and its men, will compare favourably with any Sacerdotal body in existence, to wit, the Presbyterian Church. In the medical profession we have a model of what all professions ought to be—viz., varying grades of distinction which might be called "academical." But we have a common platform on which every member meets on terms of the strictest equality—viz., as registered medical practitioners. Mr. Kent alludes to men being fully fledged, "no matter how poor his degree or diploma granted by one of the numerous licensing bodies" "being looked on by people at large as qualified." And I beg to ask—Why not? A time has been, it is true, when English qualifications were only limited, *i.e.*, a physician was strictly such, a surgeon also, and an apothecary simply an apothecary. But let Mr. Kent take note that that sort of affairs did not apply to every part of the United Kingdom. In Scotland it was unknown. Every medical qualification was and is complete as regards examination, and in certain bodies, as regards the indubitable legal rights, to act as a fully qualified medical man. To make Scotch and Irish qualifications of no effect in England is to return back to the old territorial system, which has had its day; and it will, if returned, be found to cut more ways than one. It is quite well known that the medical acts of 1858 and 1886 are founded on the understanding of the full force of each qualification being fully recognised in Her Majesty's dominions, and the Apothecaries Act of 1815 is also subject to this proviso now. All this hitherto has been held to be reform in the true sense. According to Mr. Kent we are to be again reformed by re-adopting the rules of byegone centuries. I decline to follow him in his comparison of the Scotch, English and Irish diplomas and degrees. I am perfectly prepared to do so if he wishes a controversy on the subject, but my object in this brief paper is merely to confute, as briefly as may be, what must be pronounced a series of arguments founded on false premises. At the present time in the medical profession, nothwithstanding the feeble cries of reformers, we have a bond of sympathy and union, which is, I might almost say, envied by the other two great professions, and by the clerical more than any. I ask the question would this clipping up of the medical profession into grades and classes, this dissolution of the bond of equality lead to anything else than perpetual strife? I venture to say that the corporate unity and equality of our profession is a thing we ought to value and perpetuate.—Yours truly, JAMES GILROY, M.D.

Waterheath, Dumfrieshire.

NEW INFLATABLE DILATOR.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

DEAR SIR,—In THE PROVINCIAL MEDICAL JOURNAL of December 1st, appears a description of an inflatable dilator to which is attached the name of Dr. John Ward Cousins.

This instrument cannot be styled "new," as I have had it in use for many years, and in my paper on "The Treatment of Hæmorrhage after Rectal Operations," which was published in the *British Medical Journal* of December 13th, 1888, I gave an illustration of it.

I am, yours faithfully, SAMUEL BENTON.

Bibliographical Record.

BOOKS, PAMPHLETS, ETC., RECEIVED.

Report on Hydrophobia. pp. 8. By Charles W. Dulles, M D. Reprint from Transactions of the Medical Society of the State of Pennsylvania.

On Certain Disregarded Effects of Development, chiefly in relation to the Curves of the Spine. pp. 20. By T. W. Nunn, F.R.G.S. London: John Bumpus, 350, Oxford-street.

L'Enseignement et l'Organisation de L'Art Dentaire aux Etats-Unis. Rapport addressé a Monsieur le Ministre de L'Instruction Publique. Par Dr. Kuhn. pp. 300. Paris: Octave Doin, 8, Place de' L'Odean.

The Medical Profession in the Three Kingdoms, in 1887. pp. 385. Carmichael Prize Essay of £100. By Thomas Laffan, M.C.P.I. Dublin: Fannin and Co.

Hunterian Lectures on Tension, as met with in Surgical Practice, etc. By Thomas Bryant, F.R.C.S. London: J. and A. Churchill, Burlington-street.

The Pathology and Treatment of Displacements of the Uterus. By Dr. B. S. Schultze. Translated from the German by Jameson J. Macan, M.A., and edited by Arthur V. Macan, M.B., etc. (*illustrated*). London: H. K. Lewis, 136, Gower-street.

Lionel S. Beale

THE

Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VIII.] FEBRUARY 1, 1889. [No. 86.

Our Portrait Gallery.

LIONEL SMITH BEALE, M.B., F.R.S.

LIONEL SMITH BEALE, now senior Physician to King's College Hospital, and Professor of the Principles and Practice of Medicine in King's College, and formerly Professor of Physiology, and of General and Morbid Anatomy (seventeen years), and afterwards Professor of Pathological Anatomy (eight years), was born in London in 1828, and educated in King's College School, and in the medical department of King's College. He was elected a Fellow of the Royal College of Physicians in 1859; he is also an Hon. Fellow of King's College; a Fellow of the Medical Society of Sweden, of the Microscopical Societies of New York and California, the Royal Medical and Chirurgical, the Microscopical, and Pathological Societies. He was formerly President, and is now Treasurer, of the Royal Microscopical Society, and has been President of the Quekett Club; Member of the Academy of Sciences of Bologna; Corresponding Member of the Académie Royale de Medécine de Belgique, etc.

Dr. Beale is the author of several works on medicine, physiology, medical chemistry, and the microscope. Among these works are "The Microscope in its Application to Practical Medicine," "How to work with the Microscope." In the preface to the first edition of the latter work, he says: "An earnest desire to assist in diffusing a love for microscopical enquiry, not less for the pleasure it affords to the student, than from a conviction of its utility and increasing practical value in promoting advancement in various branches of art, science, and manufacture; a wish to simplify, as far as possible, the processes for preparing microscopical specimens, and the methods for demonstrating the anatomy of different textures; and the belief that many who possess microscopes are deterred from attempting any branch of original investigation solely by the great difficulty they experience in surmounting elementary detail and mere mechanical operations, are my chief reasons for publishing this elementary course of lectures, which was delivered during the past winter." This work has been through several editions. Also, "Structure of the Tissues of the Body;" "Protoplasm; or, Life, Matter, and Mind;" "Disease Germs: their supposed and real Nature, and on the Treatment of Diseases caused by their Presence;" "Life Theories: their influence upon Religious Thought," 1871; "The Mystery of Life: Facts and Arguments against the Physical Doctrine of Vitality, in reply to Sir William Gull," 1871; "On Life, and on Vital Action in Health and Disease." In the works just enumerated Dr. Beale has advanced arguments against all physical theories of life, and has contended that in every form of living matter, from the very lowest to the highest, there is incontrovertible evidence of the working of a force or power belonging to a category quite distinct from that which includes material forces. In fact, that there is really a *vital power* which operates only during life, and is peculiar to living things, which temporarily directs and controls matter and its forces, decomposes chemical compounds, builds up new substances, forms and arranges while the living state lasts.

Among Dr. Beale's medical works are: "The Anatomy of the Liver: Urine, Urinary Deposits, and Calculous Disorders" (four editions); "Urinary and Renal Derangements and Calculous Disorders: Diagnosis and Treatment;" "One Hundred Urinary Deposits," in eight sheets; "On Slight Ailments;" "Our Morality and the Moral Question." He has contributed several memoirs to the Royal Society, "On the Structure of the Liver," "On the Distribution of Nerves to Muscle," "On the Anatomy of Nerve-Fibres and Nerve-Centres," "On the Termination of the Nerves in the Papillæ of the Frog's Tongue," etc., which are published in the Philosophical *Transactions*, and in the *Proceedings* of the Royal Society. He has also contributed several memoirs to the Medico-Chirurgical, Pathological, and Royal Microscopical Societies, as well as papers to many of the journals, and has published pamphlets upon subjects of special interest.

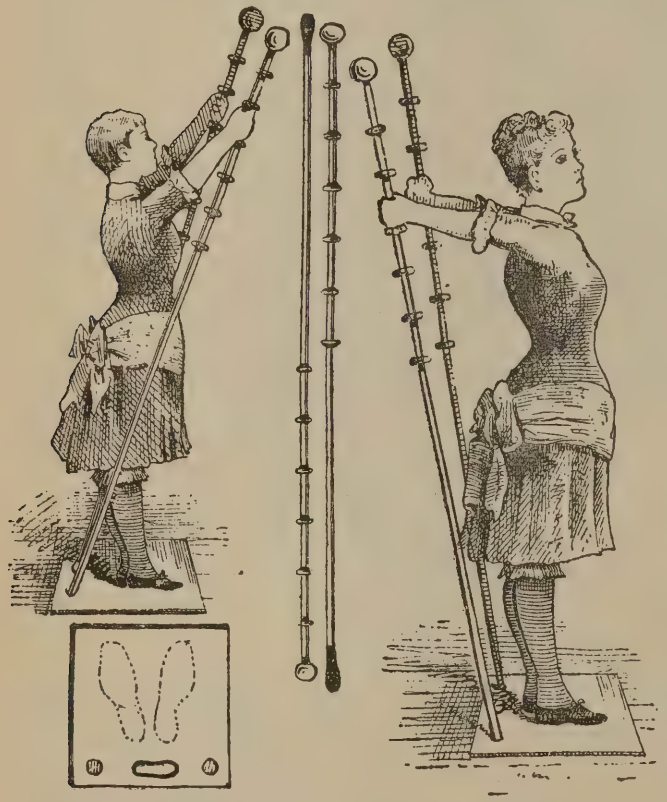
GYMNASTICS FOR LATERAL CURVATURE OF THE SPINE.

By A. W. Mayo Robson, F.R.C.S.,

Hon. Surgeon Leeds General Infirmary; Lecturer on Practical Surgery at the Yorkshire College; and Hon. Consulting Surgeon Batley Hospital.

I have been lately recommending with advantage, in cases of slight lateral curvature of the spine, round shoulders, and contracted chests, the use of a simple apparatus invented by Mr. R. Parke. The exercises seem so simple, and so efficient in developing the muscles, expanding the chest, and strengthening the spine, that I think they are worthy of being brought before the notice of the profession.

The apparatus consists of two upright poles, weighted at the top, and working on a pivot at the bottom, the patient



standing on a square board with indentions for the feet, so that the position may not alter. The apparatus is very simple and ingenious, and in its employment there is no violent action, nor any danger of over-strain. The accompanying drawings represent some of the positions. The patient stands on the foot-marks of the board, placing the poles in the sockets behind and external to the heels; he then grasps the poles firmly at the height of the shoulders. The first exercise consists in bringing both poles simultaneously to the shoulders, and thrusting them sharply forwards, which is repeated a number of times. The second exercise consists in bringing the poles simultaneously to the shoulders, and thrusting them out sideways. In the third exercise the poles are brought to the shoulders, thrust out in front, brought back, thrust out again sideways, and again brought back. The fourth exercise—which to me seems the most important, so far as the spine is concerned—consists in grasping the poles between the two lowest rings, and holding them out in front to the full extent of the arms, the tops of the poles touching, then swinging them back until they knock behind, taking care the elbows are kept straight and the body erect. The poles are made to strike both back and front each time. This is repeated a number of times, and is employed with the hands placed in all the other rings until the top is reached. The exercises are made more interesting and less monotonous if accompanied by music.

It seems to me that by the last exercises especially, both the muscles going from the chest to the arm at the front, and from the spine to the arm behind, are regularly and systematically exercised, and that the erect position, which must necessarily be observed during the drill, tends to develop the erector spinæ; but whatever be the mode of action, I am convinced that the effect is good, provided, of course, that there be no organic disease of the spine, and that the weakness is simply fractional.

CASES OF UNILATERAL SYPHILITIC AFFECTION OF THE SPINAL CORD.

By Henry Handford, M.D., M.R.C.P.,

Physician to the General Hospital, Nottingham.

The following three cases are of interest from the illustration they afford of the distribution of the sensory and motor paralysis, and, still further, as showing the remarkable degree of recovery which is attainable under favourable conditions. It is stated that in unilateral lesions below the middle of the dorsal region *sensation and motion* may be affected on the *same* side. In Case 1, sensation was manifestly more diminished on the side opposite the lesion, and so far as it goes, this case does not lend any support to the statement. But in all three cases the results were somewhat complicated by secondary softening lower down. This probably accounts for the somewhat rapid onset of complete paralysis in the latter two cases.

Case 1.—J. C——, æt. forty-five, was admitted into the surgical wards of the Nottingham General Hospital on March 30th, 1886, complaining of retention of urine and loss of power in the right leg. On April 6th he was transferred to my care. He had never been very robust; had been accustomed to drink a good deal, and had syphilis twenty years ago. Nearly a year before admission his right leg began to fail him while running. He had at one time been a professional long-distance runner. Three months ago he complained of indefinite pains in the chest and abdomen, and about two months later he had retention of urine. He was taught to pass a soft catheter, and continued to go about; but in a week or so later the right leg failed rapidly, and soon became quite powerless. Afterwards the left leg was affected also, but to a very much slighter degree. Sensation was much dulled in both legs, but was not quite absent in either; it was most diminished in the left. He also had loss of control over the rectum. He died in a few days of diffuse pelvic suppuration secondary to cystitis. After I saw him he was never in a condition to make a very precise examination of the affection of sensibility. There was no rigidity of the limbs. At the inspection, twenty-eight hours, *post-mortem*, a growth was found rather below the middle of the dorsal region. It was adherent to the inner surface of the dura mater, and involved the cord on

the right posterior aspect, extending into about one-third of the right half. There were no other growths, and no affection of the brain. The cord was softened and almost diffluent at the commencement of the lumbar enlargement. Diffuse suppuration was found on the left side of the pelvis, and was probably the immediate cause of death.

The illustration shows the general arrangement of the growth. Though adherent to the spinal dura mater it did not appear to have arisen from it. Its origin was probably in the pia mater, or in the cord itself. It bore considerable resemblance in its microscopic appearance both to a sarcoma and a glioma; but all the circumstances taken together make its syphilitic nature hardly open to doubt.

[From a camera-lucida drawing, magnified sixteen diameters, and reduced two-thirds. Although the growth penetrates the substance of the cord involving the posterior horn of grey matter and part of the anterior, the outline of the cord is still preserved.]

Case 2.—T. W——, æt. thirty-four, railway labourer, was admitted on August 12th, 1884, with complete loss of power in both legs. He had well-marked syphilis two years ago. His illness began nine days before admission with difficulty of passing water: then he dragged the right foot. He said he could not keep the toes off the ground. He had no pain. After three days he was obliged to keep his bed, and could not move his legs at all, and had retention of urine. He required the regular use of a catheter, but never had incontinence of urine. He did not come under my charge until four or five months after his admission. It is doubtful whether the loss of sensation at first was complete and equal on the two sides, but it is clear that two or three months before he came into my hands sensation was much better in the right leg than in the left. When I saw him first, in December, 1884, he could only slightly move the left leg, but could draw up the right freely, and just raise the heel from the bed. A careful examination of the sensibility was made. He did not detect the the touch of a feather so readily on the left leg as on the right, but a touch with the finger appeared to be felt equally well on both sides. As regards pain, a prick with a pin was felt normally on the right, but on the left it only excited a sense of contact, and could not be distinguished from a touch with the finger. This condition extended as far as two inches above the crest of the ilium. Sensibility to heat and cold was examined with test tubes filled respectively with cold and with nearly boiling water. On the right they were distinguished fairly, but on the left no difference could be felt between them. Ankle clonus was present on both sides, but more marked on the right. The knee jerk was very active on the left, but could not be tested on the right, because a very violent trembling—a sort of clonus—occurred on any attempt to bend the knee. The muscles of the right leg on the slightest irritation were thrown into a state of clonic spasm, which lasted a long time. The electro-sensibility was very much diminished in the left leg—a constant current of sixty milliampères was not felt at all; a very strong faradic current was only felt because of the muscular contractions it caused. On the right side it was fairly good. The electro-contractility was diminished on the left. *The left leg is a better conductor than the right.*

By February 20th, 1885, he was able to walk with sticks, but the right leg continued in a spastic condition from tonic spasm. The left could be moved freely. Sensation had not improved in the left leg. He has a syphilitic, serpiginous ulceration on the scrotum. Two years later, in July, 1887, he remained in much the same condition. The right leg was stiff, and he could not walk without a couple of sticks. He still required the use of a catheter.

He improved greatly at first, under antisyphilitic remedies; but though these have been continued at intervals for three years or more, he has latterly remained at a standstill, and no further improvement seems probable. Still, when it is remembered that at one time he had not the slightest power of movement in either leg, the ability to walk, even though with the aid of sticks, is a vast improvement.

Case 3.—G. T——, æt. thirty-five, a porter, was admitted under my care on July 30th, 1887, with complete loss of power in both lower extremities, and incontinence of urine and fœces. No direct evidence of syphilis could be obtained from the patient, but he admitted having a sore on the penis a few years ago, though he attributed it to an injury. His wife, however, was under my treatment as an out-patient, with a severe attack of syphilis, between two and three years ago. The patient's illness began with pain about the middle of the back, two months before his admission into the hospital. There had been no exposure to wet, and no unusual exertion. He continued his work as a porter for a week, but while carrying a weight on his shoulders a severe pain *suddenly* shot down his right leg, and he had to discontinue his work. Next morning he was better, and attempted to work again, but pain down the right leg *suddenly returned*, and nearly made him fall. He was able to walk home, and attended as an out-patient for a short time, complaining of loss of power in the right leg and pain in the lumbar region. He was then laid up at home with complete loss of power in the right leg before the left was affected at all. Very shortly afterwards he lost both use and feeling in the left leg, and also all control over bladder and rectum. On admission he had complete loss of power and of sensation in both legs, a bed sore as large as the hand over the sacrum (leading later to exfoliation of small portions of bone), and loss of control over bladder and rectum. There was no constant dribbling, and on examination of the rectum the sphincter was found to contract. It was evident, then, that the lesion was above the lumbar centres, and had not destroyed them. He could not move the legs in the slightest degree. He was treated by antisyphilitic remedies, and on September 7th the report in the case book runs: "Plantar reflexes, and common sensation in feet and legs returning; localises correctly, but requires a moderately firm touch. Knee jerks exaggerated on both sides. About three inches below the crest of the ilium sensation on the outer part of the left thigh becomes deficient. In the middle line there is a sharp line of demarcation about three inches below the umbilicus, above which sensation is good, and below, deficient. On the left side he can feel about two inches lower down than on the right."

By January, 1888, the large bed sore which the patient had on admission was nearly healed. Sensation continued to improve, and was better in the left leg than the right. There was some tonic spasm in both legs, and they were also subject to clonic spasms, being sometimes forcibly jerked up, and at other times jerked out straight again,

Voluntary motion was returning. He could sit in a chair, but could not stand without support. Shortly after this he went out, and was lost sight of.

There could be no doubt that the lesion here was a gumma, probably arising in the dura mater, and affecting the cord secondarily, involving chiefly the right side in the lower dorsal region, and leading later to softening (myelitis). The *sudden* onset of symptoms arising from a growth is curious, but is a phenomenon not unfrequently met with in such cases, and also in intestinal obstruction from growths in the intestine.

SUGGESTIONS FOR THE MORE RATIONAL THERAPEUTICAL TREATMENT OF RESPIRATORY AFFECTIONS.[1]

By C. Clark Burman, L.R.C.P., L.R.C.S. Edin.,
Belford, Northumberland.

(*Continued from page* 8.)

The indiscriminate use by the public of quack nostrums for the relief (?) of respiratory affections—from simple cough to the advanced stages of phthisis—cannot be too strongly condemned. Upon our profession rests the duty of enlightening the public, so as to lead to the discontinuance of such nostrums. This is but reasonable, since our physiological and therapeutical knowledge—independent of our relations, professional or otherwise, with those suffering from affections of the respiratory organs—would point us out as the chief exponents of their danger and fallacy. The use of these noxious agents—noxious in so far as their most active constituent, opium or sedatives in some form or other, is concerned (though disguised under the names of simple or harmless substances, aniseed, linseed, or horehound, for instance, or by some high-sounding and fanciful appellation)—in the domestic treatment of the before-mentioned affections, and especially among children, is simply monstrous.

It is to be regretted that such conduct is attributable not only to the ignorant and uneducated, but also to the intelligent, and even the higher classes of society. Can we wonder at this? Take up any so-called religious publication, and we find its advertisement pages filled with the published statements of those who have experienced the benefits of these panaceas, attested by all classes of society, from the peer to the peasant, inviting personal reference for further accounts of their remarkable virtues. Naturally enough, the most is made of cases which "have tried all the well-known specialists in such diseases;" "had been given up by the faculty;" "had tried every other remedy, and found them all fail," until Providence directed their attention to the nostrum in question; and, though doubting its efficacy, "their experience has been so remarkable, that they deem it a duty which they owe to their fellow-men to publish what great things it has done for them." Not only are the public led astray by these means, but we find learned (*sic*) members of the theologica profession "preaching" on Sundays, and "practising" during the rest of the week on the credulity of the public, who naturally suppose that the prefix Rev. stamps them as genuine, and that the advice and remedies are but a practical exposition of that greatest of all the virtues, "charity," which zeal for their profession leads them to adopt as a means to an end. In many cases—it might be said, even in all—the end in view is not so much the "charitable" object of relieving suffering, as of increasing the worldly prospects of the reverends in question. At the least, we may say, the latter object is the primary consideration, the other being quite secondary. With these incentives to error so widely diffused and so well disguised, it behoves us as true members of our profession to use our influence with the public, both by lectures and private conversation, to remedy this increasing evil. But before proceeding to cast the mote out of our brother's eye, we must be mindful of the beam in our own. Do we as a profession admit the "beam in our own eye?" Is it a fact, known, of course, only to ourselves, that while the profession as a body denounces these quack nostrums because of their active ingredients, many of its members daily prescribe for their patients drugs which, when consumed by a patient in some quack remedy, are declared injurious, but which, having the sanction and authority of a duly qualified member of the profession, become, in his eyes at least, perfectly justifiable and legitimate? Now, though far from wishing to charge this folly upon the profession as a whole, I feel convinced it exists in a sufficient degree among us to call for remark, and should lead us to consider if this *routine* treatment of disease—for it is here that the mischief lies—is justifiable in these days of precise diagnosis, assisted by so many valuable instrumental aids, and possessing as we do so much greater, though far from perfect, acquaintance with therapeutics founded upon clinical research and physiological experiment. To stop a cough by sedatives is one thing; but to seek out the exciting causes, and to apply suitable remedies, is quite another thing—not so easy, perhaps, but much more scientific. Such treatment as the former I have no doubt might be looked upon as justifiable by our predecessors, when symptomatic treatment was general, but such an argument can hardly hold good now. The indiscriminate use of sedatives in respiratory affections is derogatory to us, who are so far beyond our predecessors in matters of therapeutics. Take, for instance, the use of opiates in children. Under ordinary circumstances they are not admissible, on account of the cerebral congestion produced by the drug. It is almost unnecessary to remark how exceedingly frequent these congestions are in respiratory affections of children; hence, the administration of drugs with these tendencies is usually, though not universally, abandoned.

Let me take a case in illustration of the "routine" practice I here deprecate. A child is suffering from a troublesome hacking cough, accelerated breathing, slightly increased temperature, with general restlessness interfering with sleep; no marked physical signs are apparent upon an examination, and this is far from unusual among children in the earlier stages in which the constitutional symptoms are out of all proportion to the local disturbance. We content ourselves with a diagnosis of some slight catarrhal affection, and perhaps carrying out the same idea in reference to children as we do in adults, that the calmative and sudorific action of an opiate will exactly meet the case,

[1] [To the writings of the late Dr. Milner Fothergill, whose recent decease the profession still mourns, I must express my great indebtedness, not only for suggesting the line of thought I have endeavoured to follow in this paper; but also, as the readers of his works will observe, by the numerous quotations, for the actual words in which to express my meaning. I take the opportunity, therefore, at this stage to fully acdnowledge this assistance in a general way, and thus avoid a repetition of references. For further information I would suggest a careful perusal of the following works of Dr. Milner Fothergill: "The Antagonism of Therapeutic Agents," "Chronic Bronchitis," "Handbook of Treatment," "The Physiological Factor in Diagnosis," and "Gout in its Protean Aspects."]

we fall into the error of prescribing a mixture combining an expectorant with some opiate, such, for instance, as:

℞. Vin. Ipecac ʒ ii.
Tinct. Camph. Co. ʒ iij.
Aquam ad. ℥ iv.
M. fiat mist. Sig. ʒ i. vel. ʒ ij., pro re nata.

Now, let us question ourselves, if such a prescription is either scientific or even judicious. The smallness of the dose of opium seems to justify its use; but though we guard against the danger we are aware of—cerebral congestion—are we not overlooking the not less equally significant fact of idiosyncrasy? *All children bear opium badly;* but some exhibit toxic symptoms from most minute and apparently safe doses; the exact converse is true of belladonna. This calls to my mind the question said to have been asked by an examiner of his candidates: "How much opium would you administer to a child a year old?" Some answers were so carefully calculated that the dose mentioned savoured of homœopathy; but evidently, the most infinitesimal dose did not satisfy the examiner; and when one candidate answered "*none*," the hearty approval of his questioner showed the correct answer had been given. I do not wish it to be understood from this episode that I agree with the said examiner: I admit he erred, but in my opinion on the safe side. There is no doubt that opium, in one of its many forms, is not only useful, but absolutely necessary in some ailments of children; but I decidedly exclude respiratory affections, particularly acute or sub-acute inflammatory manifestations of disease in these organs.

To return to our illustration. Let us analyse the symptoms. Suppose no physical signs are present, we have (1) increased temperature; (2) cough, frequent and troublesome—irritative, if you like, but dependent upon conditions removable without the aid of opium. The congested state of the air passages in the initial stages of catarrh renders them more susceptible to the irritation of the inspired air; the slight, though scanty and tenacious secretion characteristic of this early stage, of necessity excites repeated and frequent acts of coughing for its removal; (3) general restlessness: this is a natural accompaniment of the increased temperature, due to the heated blood travelling through the cerebral vessels, which, as we know, are, during the rapid development of the brain, proportionately more numerous and better filled. The slight respiratory embarrassment, as evidenced by the accelerated breathing, to a certain extent permits the venous cerebral vessels to become somewhat congested. The proportionately greater quantity of arterial blood—its increased temperature and its possible impurity on account of the restricted action of the skin and kidneys, together with the slight though apparent fulness of the cerebral veins, as shown by the somewhat congested and suffused eyes and mental hebetude—these symptoms, when analysed, afford the true indications for treatment—viz., to reduce temperature, promote expectoration, and increase the action of the skin and kidneys. Can these indications not be met in a manner which, though efficient, shall not be open to the objection which opium, under the above circumstances, certainly possesses? I think they can; for by means of a combination of saline diaphoretics and expectorants we may attain the desired end without running any risk from opium, owing to idiosyncrasy, etc., such as:

℞. Liq. Ammon. Acet. ʒ iv.
Vin. Ipecac. ʒ iss.
Sp. Eth. Nit. ʒ i.
Aquam. ad. ℥ ij.
M. fiat mist. Sig. ʒ i., vel. ʒ ij., 3 tis. horis.

We look for relief, first, by means of the diaphoretic action of the acetate of ammonia, which, by dilating the cutaneous capillaries, brings a larger quantity of blood into the heat-losing area; radiation reduces its temperature. The action of the sudiparous glands purifies the blood, and we find as a consequence that the slight congestion of internal organs, brain included, which resulted from the contracted cutaneous vessels, is relieved. The vitiated state of the blood is improved, and the temperature falls. The diuretic further aids the skin; and though the quantity of urine may not be appreciably increased, owing to the excessive secretion from the skin, its solid constituents are proportionately greater, and the oxidised products are eliminated. Independent of the assistance of the ipecac. as a diaphoretic, we have its specific action upon the bronchial mucous membrane; the secretion becomes more plentiful, less tenacious, and consequently the cough, which before was troublesome, is now not only effectual, but less frequent, and relief is obtained by the removal of the accumulated secretion. The use of poultices to the chest would still further help us by withdrawing from the lungs an increased quantity of blood, and thus relieving the pulmonary circulation. A room having its temperature kept about 60° or 65°, and if the cough be very troublesome and dry, the introduction of steam into the atmosphere will materially assist in bringing about a satisfactory change in the patient. Such, then, in my opinion, would be a thoroughly scientific, as well as rational therapeutic treatment for a case of catarrh threatening to become bronchitic, in children.

The foregoing remarks are illustrative of the line of treatment which the progressive science of physiology is year by year teaching us; and while admitting that clinical observation and treatment founded upon such observation is undoubtedly valuable, I also maintain that it is neither valuable nor trustworthy unless it corroborates some of the truths which physiology had previously advanced. Thus only can we feel satisfied of the stability of the foundation on which we are building our system of therapeutics, and look forward to the permanence of such a system as shall embody the clinical corroboration of physiological data. Here we see how much one branch of medicine depends upon the development of other branches, and how true advancement is only in proportion to the consolidation of knowledge arrived at in the physiological laboratories and at the bedside. The following extract from an article in the *British Medical Journal* of February 2nd, 1884, appears to confirm these views:—

"The whole course of therapeutics is strewn with the wrecks of remedies which have been foisted upon the profession by the supposed results of clinical observation. Perhaps nothing is more delusive than a fragmentary and ill-digested collection of clinical facts. The sources of error are too numerous, and the conditions too complicated, to allow clinical observations to determine any important conclusion until many facts, well observed and carefully collated, have been brought to bear on the question. More especially must this be the case when the clinical observations contravene what are supposed to be well-demonstrated scientific facts, as in the case under consideration. Science will be of little avail in promoting the advancement of the medical art if facts established by research and observation are to be lightly set aside by clinical observations short of absolute certainty. It seems far more reasonable to conclude that clinical experience will, in the end, conform to scientific demonstrations."

The use of respiratory stimulants, which I am endeavouring to advocate, has its foundation in well-established scientific facts; hence, the clinical *follows* the scientific—the proper order.

As members of a profession which owes most of its progress, both medical and surgical, to the labours of those investigating the secrets of nature as revealed in the animal creation, and to whom experimental enquiry is essential to the thorough understanding and perfecting of observations already made, we cannot but deplore the false position occupied by some, who by their agitation, have so bound the hands of these workers as to make the study of practical physiology repugnant to them, and obliged the profession generally to obtain much of its information, so essential to progress, from continental laboratories. The ability of the profession in our country is beyond question, but the means for scientific research are wanting, owing to an act of legislation based upon ignorance, misunderstanding, and a culpable want of confidence. How would the circulation of the blood have been discovered, with all the knowledge flowing from its discovery, had Harvey not performed his experiments? What was Jenner's discovery founded upon, but experiment? How could ovariotomy have exercised such a beneficial influence upon our women but for Sir Spencer Wells' experiments? The fact of a Vivisection Bill having been passed in England will remain a stigma upon its people, who claim to be recognised as the most enlightened and progressive in the world. No greater argument for the political powerlessness of the profession need be advanced than the passing of such an Act; and until the profession is united (which, I regret to say, even upon this question, is not the case), we can look for little respect from the public. Why, in a case in which our interests, as well as those of the public, are so trampled upon, do we look so indifferently upon our position, and sit with folded arms and see the legislative cords being drawn tighter and tighter round the most active pioneers of our science? Surely the repeal of this Act would benefit the profession and the public much more than any number of Medical Reform Bills. But my indignation at such arbitrary legislation, or, at least, the means by which such enactments were successfully passed, is so great, that I have wandered away from the main subject.

Experimental enquiry and research have done very much towards elucidating the various phenomena connected with or depending on affections of the respiratory organs; hence my digression. In the first part of this paper I attempted to explain that the knowledge thus obtained was unknown to, or, if known, despised by those who propose to treat, with so much success, these affections by a plan of treatment utterly at variance with the physiological laws as then propounded; and that even many members of our own profession either did not fully appreciate these laws, or by a plan of "routine" treatment so act as to lose the benefit derived from a thorough understanding of them and their application to a system of therapeutics. I am fully aware how difficult it is to change one's accustomed plan of treatment after a long continuance of the same, owing to our thoughts and actions having worn, as it were, certain ruts in our minds. Some startling results, hitherto unthought of, must be presented to bring about the necessary change; hence my endeavour to emphasise the dangers of administering indiscriminately certain drugs, such as chloral, opium, etc., in a class of cases which give us the bulk of our medical experience in this country, the variable climate of which, independently of other causes, tends so much to the production or aggravation of so many affections of the respiratory organs. Once let it be understood upon what grounds and by what means results so disastrous are brought about, and our natural desire to do all in our power for the benefit of those committed to our care will compel us to reconsider a course of treatment, the evils of which have been exposed by a line of argument based upon well-recognised and authenticated facts—as, for instance, the "sleep of death" induced by the exhibition, with the best intention, of a draught containing chloral.

The breathlessness of anæmia and chlorosis is but one of many other symptoms associated with the diminished number of red corpuscles in the blood. Neuralgia, so frequently met with in anæmia, was said by Romberg to be the prayer of a nerve for healthy blood. So, to a certain extent, dyspnœa is the prayer of the respiratory centre for healthy blood, but with this important difference, that the dyspnœa, for a time at least, purifies the blood. It is a sign of danger; but, fortunately, in itself also a means of averting the danger. Apart altogether from the treatment of anæmia proper by iron, which does not particularly concern us here, though some remarks upon its administration will be necessary in order that the breathlessness, one of the symptoms of anæmia, shall be effectually relieved (for this relief will go on, *parri passu*, with the increasing richness of the blood in red corpuscles), I wish principally to draw attention to the advantages of a combination, with iron, of some other drug which materially assists its action.

The generally-impaired nutritional state which the excess of adipose tissue—so often associated with anæmia, and which I explained as due to the deficiency of oxygen to burn up the hydrocarbons—must not lead us to overlook, affects not only the voluntary muscular system, as evidenced by the fatigue and weariness after trifling exertion, but also the involuntary muscular fibres of the heart, intestines, etc., proof of which is found in the usual constipated state of the bowels and the frequency of temporary incompetence of the mitral valve due to slight dilatation of the left ventricle from its impaired nutrition. This latter cause, together with the weakened state of the respiratory muscles, undoubtedly favours the occurrence of pulmonary congestion, and must not be left out of consideration if we expect successful results to follow our treatment. The addition of strychnia to the iron mixture is specially adapted to those cases of general debility where the respiration is embarrassed. In my practice I meet annually with very many cases of anæmia, and the prescription I almost invariably adopt, unless special symptoms indicate otherwise, is this:

℞ Liq. Ferri, ʒ iii.
Liq. Strychnia, ʒ i.
Sp. Chlorof., ʒ ii.
Infus. Quass. ad., ℥ viii.
M. fiat mist. Sig. ℥ js. ter in die, ex. aq. post cibum.

By such a combination we attack not only the condition of the blood, but, by increasing the tone of the muscular system generally, voluntary as well as involuntary, we aid the respiratory and circulatory functions in an extremely favourable manner.

If we have evidence of functional incompetence of the mitral valve, the addition of six minims or so of tincture of digitalis, or strophanthus, is valuable; and if palpitation be present, a belladonna plaster over the cardiac region meets all the indications for treatment.

In whatever form iron is given, it should be well diluted; and nothing answers the purpose so well as a good draught

of cold water taken after each dose. In the dilution of the constituents of the natural waters, both chalybeate and alkaline, lies the secret of their success; and, but for the change of place and scenery, with the mental influences resulting therefrom, we can carry out a "spa" line of treatment under home influences; an object not unfrequently of great importance.

Another point about the administration of iron as a pure hæmatic is that it should be given *after food*, and digested with it. It is said that the gastric irritability, or perhaps gastric ulcer, so frequently associated with pronounced anæmia, contra-indicates the use of the astringent preparations of iron. Such is certainly not my experience. The above combination rarely fails me unless some decided irritation with vomiting exists, which I subdue with bismuth, prussic acid, etc., and then commence the iron mixture. We have, however, in dialysed iron a most satisfactory preparation in case the preceding form is unsuitable, and especially in *young* people—grown up children—where the exhibition of Parrish's syrup is not indicated.

In some cases of anæmia, when iron in any form seems to do no good, arsenic, as pointed out by Dr. Byrom Bramwell, is a most useful remedy. It is a powerful alterative and blood tonic; and its efficacy in procuring more perfect elimination of waste, and so more perfect nutrition of the body, is well marked. The use of the drug among the mountaineers of Styria, for the purpose of improving and strengthening the respiratory powers, is well known; and it certainly is useful in those cases of anæmia with slight apical consolidation; but whether its effects are due to any direct action upon the pulmonary tissue, or to its alterative properties and the consequent increased nutritive activity, I cannot say.

The anæmic condition frequently associated with the so-called blood poisons, such as gout, rheumatism, syphilis, malaria, mercury and lead poisoning, etc., require for successful treatment the combination, with the iron, of the so-called specifics for these affections. In gout and rheumatism, for instance, alkalies must be administered. We would give the bicarbonate of potash, or citrate of lithia, with the ammonia-citrate or tartrate of iron; and in adding the strychnia, which in these cases is equally useful, there is one point worthy of remembrance—that strychnia, an alkaloid, should never be prescribed with an alkali; being soluble in an acid, as in liquor strychnia, it is precipitated by the excess of alkali, and hence might become a source of danger. When prescribing alkalies, the tincture of nux vomica, in ten minim doses, should be substituted.

In syphilis, when, in addition to the anæmia dependent upon the dyscrasia, the administration of mercury is often necesssary for a lengthened period, we have a double source of danger to contend with—the original affection, and the remedy employed—for mercury produces marked anæmia when long continued; so that in broken-down syphilitic constitutions, or when prescribing an extended course of mercury, iron should be combined with it, as—

℞ Liq. Hydrarg. Bichlor.
Liq. Ferri, āā ʒiii.
Infus Quass., ad. ℥viii.
M. fiat mist. Sig. ℥ss. ter in die.

Or in children, hydrarg. c. creta, night and morning, and the syrup of iodide of iron through the day.

In malaria, where we meet with most pronounced anæmia, the addition of quinine to the iron becomes a necessity, in order that the destructive tendency of the malarial poison upon the red corpuscles may be successfully prevented.

The treatment of asthma naturally resolves itself into that of the paroxysm and the interval. Professional opinion is now almost unanimous upon the etiology of idiopathic asthma, but the multitude of remedies which the various text-books prescribe, makes its treatment a matter of difficulty. Consequently, we find the greatest divergence of opinion regarding it; almost every practitioner having his own "specific" for cutting short the paroxysm. One maintains that a cup of hot "*café noir*" supersedes all the remedies of the pharmacopœia; while another finds a combination of almost all the known anti-spasmodics necessary to bring about a similar result. Between these extremes I think the truth will be found. It is reasonable to suppose that the speediest results will be brought about by remedies acting directly upon the spasmodically-contracted bronchi; hence the universal application of drugs in the form of vapour, which are brought into actual contact with the bronchial mucous membrane by means of inhalation. This undoubtedly holds true only so far as the inspiratory force is capable of doing the part of carrier. We have seen that when the paroxysm is fully developed, the inspiratory act only succeeds in bringing air into the trachea and larger bronchi, since auscultation, during a paroxysm, does not reveal vesicular breathing; consequently, much of the good expected from the drug cannot be realised; and in this lies the explanation of failure and consequent disregard for certain drugs, used when conditions are unfavourable for the development of their action. It is obvious, then, that remedies in vapour, whatever they may be, which require, for the exercise of their beneficial properties, actual contact with the contracted bronchi, must be used *before* the inspiratory function is so much interfered with as to prevent this; otherwise the vapour will only enter the trachea and larger bronchi, and fail to give relief. To a certain extent they may be effective, as the absorptive properties of the mucous membrane still remain; and for this reason inhalations, such as chloroform, nitrite of amyl, etc., can be used during the height of the paroxysm, because the surface, though small, with which they come in contact is absorptive; and being themselves readily absorbable, their action is speedily manifest. But with drugs which are less easily absorbed, failure only can be looked for; and then we have recourse to remedies which act after entering the circulation. Before entering upon the consideration of this class of drug, let us for a moment look at the position—an intermediate one—held by emetics. The administration of an emetic, say of ipecac. wine, may cut short an attack; but how does it effect this? Is it by means of its well known action upon the bronchial mucous membrane, or must it be looked upon in the light of a revulsant—a transference of nervous energy to another part of the economy? Probably from the rapidity with which relief follows emesis, we may conclude it is due to the latter cause. Emetics are undoubtedly useful, and perhaps most of all in those cases of asthma due to gastric irritation, set up reflexly, from a supper or some indigestible article of food, the removal of which by means of emesis is the chief indication of treatment, taking, of course, for granted that no contra-indication, such as cardiac or serious pulmonary disorder, etc., is present. When conditions such as these exist, emetics become absolutely dangerous.

Thus, while granting the early use of vapours in some form or other to be the best means for *our patients* to use, *we* certainly possess the power of almost instantaneously

cutting short a paroxysm of idiopathic asthma by means of the hypodermic administration of a combination of morphia with atropia: gr. $\frac{1}{4}$ to gr. $\frac{1}{3}$ of the former, and gr. $\frac{1}{100}$ of the latter. According to Dr. J. G. Oliver in the *Practitioner*, January, 1876, "Morphia and atropia are superior to morphia alone; the good effect is more speedy and complete, and they produce no depressing gastric disturbance. The very frequent use of the injection does not appear to injure the general health. Speedy relief. The effect is generally declared in five minutes, in the form of comfortable sleep and quiet breathing. The most intense attack has given way completely in from fifteen to twenty minutes."

The advantage of the combination of these two drugs I will discuss when considering the physiological action of the respiratory stimulants; for the present, it will suffice to say that hypodermic injections of these remedies may be used with perfect safety in cases of cardiac asthma; and I have repeatedly verified the above statement of Dr. Oliver; the atropia allowing the morphia to act as a relaxant of the spasm, without depressing the already weakened respiratory centre.

The leaves of several plants of the solanaceous order—stramonium, tatula, belladonna, hyoscyamus, and tobacco, together with lobelia, form the chief medicinal constituent of the many forms of cigarettes used for inhalation purposes. The fumes arising from burning nitre paper, or paper evolving peroxide of hydrogen, are often very useful. The vapour of ammonia can be similarly used, or a solution painted upon the pharynx with a brush, but this method of treatment must be conducted carefully, or results such as those described by Trousseau in 31st Lecture, vol. ii., might cause great alarm and anxiety.

The treatment during the interval is of great importance, and towards this we have the opinion of many eminent clinical authorities. Niemeyer holds by quinine for its radical cure, especially if the attacks are frequent, and the interval regular. Da Costa administers lobelia with hyoscyamus, and Hoffmann's anodyne (sp. eth. sulph. co.) during, and for some time after, the paroxysm, and then pays great attention to the possible reflex causes, and of the stomach particularly; giving gr. ii. of blue pill, and a dose of Rochelle salts in the morning; and then for some time a mixture of arsenic and belladonna, or gentian. Trousseau has a rather tedious and complicated plan of treatment, consisting of the administration for ten days of gradually increasing doses of belladonna, or its alkaloid atropia; during the next ten days tablespoouful doses of the syrup of turpentine; and for the last ten days arsenical cigarettes are to be smoked; while upon every tenth day one drachm of powdered yellow cinchona bark in a cup of coffee is to be taken fasting. It is to the atropia he looks for the most benefit; the others are but adjuncts. The arsenical treatment of asthma is as old as Dioscorides, who used what was in his day called "sandarach," but is now known as realgar, or red sulphuret of arsenic. The treatment by large doses of iodide of potassium is now highly praised; but with doses of one drachm, unpleasant symptoms are liable to occur, unless a small quantity of opium be given with it; and if continued for some weeks the patient must be watched, lest it impoverish the blood, and produce purpura, boils, or even carbuncle. Dr. Hyde Salter, a great authority upon asthma, looks upon stramonium as *the* remedy, used as inhalation, or given as tincture or the extract; remarking that the earlier in a paroxysm it is had recourse to, the more likely will it relieve spasm. He also recommends iron and quinine, with some mineral acid as tonics in the interval.

But of all the remedies which find the greatest favour among many practitioners, belladonna stands most prominent, and its advantages are due to its being a respiratory stimulant, thus rendering the function more perfect. It reduces the tendency to spasm, which has the peculiarity of coming on, as I remarked in my first paper, during the time when the sleep is most profound, and when the respiratory act is both shallow and infrequent.

I cannot omit the plan of forced expiration and inspiration, advocated by Dr. J. S. Monell, of New York, in the *New York Medical Record* for August 15th, 1886, for the treatment of asthma. Painting the course of the pneumogastrics in the neck with tincture of iodine has been tried with success, and so has galvanism. Dr. Thorowgood strongly advocates strychnia in complicated cases. The residential treatment of asthma is very difficult, and in the purely nervous form it is to be found out only by experience; but in many cases a sea voyage is beneficial; while if any complication, such as bronchitis, emphysema, etc., exists, a climate suitable to such complications must be advised. It is wonderful how much difference is felt by a change of only a few miles.

Asthma, occurring in connection with grave organic changes in the kidneys, or in gouty patients, will require the treatment of the interval to be conducted upon those lines most adapted to the condition of the blood causing them. This has been already fully discussed, and we must never permit the paroxysm to turn our attention away from the real malady, of which the asthma is but one among many symptoms. I may remark, however, that with the high arterial tension met with in subjects of these disorders, drugs having the property of relieving arterial spasm are often more efficacious than ordinary anti-spasmodics; and among such, nitrite of amyl., nitro-glycerine, and nitrite of sodium stand out prominently. Sedative drugs, more particularly opium, are to be avoided, on account of their power of restricting tissue change, and their interference with the eliminating properties of the liver and kidneys, organs upon the proper functional activity of which the life of patients suffering from uræmia and lithiasis, depends. Alkalies and the astringent preparations of iron, with diuretics, and, if necessary, saline purgatives to assist, must be assiduously administered during the interval; and the exhibition of all food containing an excess of nitrogenous elements must be restricted to the narrowest limits.

In old standing cases the administration of belladonna or strychnia can do no possible harm, and may with advantage be combined with the ordinary treatment; but here again I must draw attention to the danger of prescribing an alkaloid with alkalies. In Wood's treatise on "Therapeutics," 2nd edition, 1877, p. 646, I find a remark that "death has resulted from a prescription containing strychnia and iodide of potassium, all the alkaloid being taken at the last dose." In such cases, then, the tincture of nux vomica or tincture of belladonna must be prescribed.

Cheyne-Stokes' respiration being the signal of approaching dissolution in many cases, naturally admits of little in the way of treatment; but the cause of its production being so well known, the means to be adopted are such as will give increased energy to the fast-failing respiratory centre, and this is to be found in atropia. Hypodermic injections of $\frac{1}{100}$ gr. might be tried; while attention to the original disease

with which this phenomenon is associated, is not to be neglected; so that, while in many cases the heart is failing, digitalis and nux vomica must be persevered with; if uræmia is present, the vicarious emunctories must be excited to action. I have spoken of the postural treatment of those cases of apoplexy, where consciousness is long in returning, in my first part, and need do nothing more than call it again to mind, as I am more and more convinced of its utility in preventing pneumonia.

(To be continued.)

A LECTURE ON SOME OF THE CLINICAL RELATIONS OF ALBUMINURIA.[1]

By Alfred G. Barrs, M.D. Edin., M.R.C.P. Lond.,

Assistant Physician to the General Infirmary at Leeds; Lecturer on Physiology in the Yorkshire College of the Victoria University.

(Continued from page 28).

Of other uræmic manifestations, most of which are accompanied by overt signs of the renal condition upon which they depend, I propose to say only a few words touching the occurrence of hemiplegia in the uræmic state; and of this I wish to say only, that there is a form of hemiplegia occurring, perhaps more frequently than is generally thought, of a quite recoverable kind. It is important to recognise this fact, for the reason that it is transient and recoverable as distinguished from that due to cerebral hæmorrhage. It is closely allied, both in its characters and its affinities, to the paralyses sometimes seen to follow epileptic seizures. I have seen a case in which the limbs remained paralysed for some three days, and then rapidly recovered, an event which could scarcely happen in an ordinary case of cerebral hæmorrhage.

One other point in relation to fatal forms of albuminuria I should like, with your permission, to touch upon, is the question of the relation of chronic renal disease to acute nephritis, especially that, the most common form of all, the result of scarlet fever. The point is an important one in regard to the future of cases of scarlet fever in which nephritis has supervened, A question which meets us at the outset is one of some little difficulty to settle, and, that is, what are the facts which are to be accepted as conclusive of the supervention of acute nephritis in scarlet fever? Here, as everywhere else, as I have said, the question is notoriously not one of albuminuria alone. What ought we to accept as the unequivocal evidences of Bright's disease in scarlet fever? I think we may safely say that any cases of scarlet fever in which blood and tube casts appear in the urine are cases of Bright's disease. What becomes of these cases, and what relation have they to the large white kidney (I use this term in its broadest sense as being the naked-eye expression of an epithelial as distinguished from an interstitial lesion) of later life? I am not aware that it has ever been seriously suggested that cases of scarlatinal nephritis eventuate in the granular kidney of later years. There seems no reason, clinically, to connect the two, that is, at first sight, yet I venture to say that if the most recently accepted teaching in regard to the pathology of scarlatinal nephritis be true, there is much more *prima-facie* reason to believe that cases beginning in scarlet fever in childhood end in granular and atrophic change than in epithelial proliferation. My own belief is this, that in its march, acute nephritis is very much on all fours with acute pneumonia. It is undoubtedly an acute specific disease, and, I believe, runs its course as such, either to complete recovery or destruction of the patient in a comparatively definite time. Here, again, I would say that the mere presence of albumen in the urine is no indication of the presence of renal change, for the purpose of calling to your mind the fact that in many cases of scarlatinal nephritis, the urine continues albuminous for weeks or even months, when there is every reason to believe, and as the event of the case shows, that the kidney, structurally, is perfectly sound. My own belief is this, and it is, if I mistake not, borne out by the records of this and other hospitals, that chronic renal disease is chronic from its beginning, and is not the result of any acute specific change, such as that seen in scarlatinal nephritis. Dr. Wilks has said, our dread as the advisers of our patients should be, not lest their acute diseases should become chronic, but lest their chronic diseases should become acute. Many a case of so-called acute spontaneous nephritis occurring in adults after exposure to cold or alcoholism, as the case may be, will, I believe, on careful investigation, turn out to be only an acute inflammatory condition, grafted upon an already diseased and enfeebled organ; and, so when the acute stage subsides, the so-to-speak normal condition of chronic disease is observed for the first time, and the case is naturally, but erroneously, regarded as one in which an acute disease has lapsed into a chronic and permanent condition.

"But the fact," says Dr. Goodheart,[1] "strikes me how sharply renal disease, or rather Bright's disease, in the wards, falls into two groups: the one, acute disease tending towards recovery, a group consisting almost entirely of young people; the other also called acute or subacute, but apparently very little bettered by treatment, and a disease of adult life. Of fifty-six cases of acute and subacute nephritis, no less than forty left the hospital passing more or less albumen, and most of them, after a long stay, ten only left well without albumen, and seven of the ten were under sixteen years old. A fact so striking calls for some explanation. What is it? Can there be this great difference between the reparative power of the kidney in youth and childhood and in adult age? Is it not rather an essential difference in the nature of the disease that one is really acute, and the other a slow insidious form, which passes for acute solely because in its exacerbation it is liable to become associated with anasarca?"

A few words upon the prognosis in cases of Bright's disease, and I finish what little I have to say upon the albuminurias dangerous to life, and pass on to speak of those commonly called functional or physiological albuminurias.

I believe, as I have said, that cases of acute nephritis occurring in children (and these cases will almost always be scarlatinal) generally terminate in a reasonably short time in death or recovery, most commonly in the latter; they do not lapse into a chronic and prolonged albuminuria, terminating after months or years in death. Acute nephritis and subacute nephritis, occurring in adults after exposure and other trivial causes, is to be looked upon with a great suspicion that the cases are only exacerbations or acute attacks grafted upon an already diseased organ. The acute attack may or may not subside, usually it does so (that is, barring the accidents of uræmia), leaving the case one of confirmed chronic Bright's disease.

The duration of cases of chronic Bright's disease

[1] Delivered in the Post-Graduate Course at the Leeds General Infirmary.

[1] "Guy's Hospital Reports," 1883, 1884, p. 139.

depends clearly upon the amount of useful available kidney-tissue remaining, and this of course is only to be estimated by the amount of urea eliminated by the organ, and obviously not by the amount of albuminuria. The practical bearing of this observation is well seen in the case of granular kidney, an essentially patchy lesion in its march, in which the period of the case may be measured, frequently by fives, and not seldom by tens of years. Renal asthma is frequently of fatal import, showing that the uræmic condition has reached its acme. "I have no recollection of a case admitted to hospital with well-marked renal dyspnœa which did not very soon terminate fatally."[1] Adopting Dr. Grainger Stewart's[2] classification, I now pass to the consideration of the albuminurias not dangerous to life, and I may say, at once, that into this class will fall all the many cases of albuminuria which are not cases of Bright's disease. To deal with the whole of this category it is not my intention, nor is it customary to do so under the title of albuminuria. The albuminurias then, arising in the course of acute diseases and pyrexial states, such as acute pneumonia, in certain toxic conditions (cantharides, carbolic acid, etc.), in cardiac and obstructive lung diseases, will not, therefore, concern us.

The class of cases to which I allude has been designated functional or physiological albuminuria. In regard to the terms functional and physiological, the former clearly indicates what I suppose we all believe, that there is an albuminuria which is not dependent upon structural change in the kidney in an ordinary sense; the latter term physiological is useless, and commits us to a position which is almost, it seems to me, a contradiction in terms. Some few observers, it is true, have averred that albumen or some allied proteid substance is, in the minutest traces, a normal constituent of the urine. These statements are wanting confirmation, and while this is so we may dismiss the term physiological as untenable. If, of course, all manifestations on the part of organs whose structure is normal are to be called physiological, then there is a physiological albuminuria; epilepsy would be a physiological convulsion; uræmic dyspnœa a physiological dyspnœa. It need scarcely be said that such a use of terms is misleading, to say the least of it, and means only a hair-splitting scarcely worth the time spent upon it.

The conditions under which albumen appears in the urine other than those of Bright's disease, poisons, pyrexial states, cardiac disease, etc., are very various, but are, on the whole conditions, not indicative of any serious disturbance of the bodily functions, and are not easily placed in any of the ordinary categories of diseased states. They include conditions of exertion and fatigue, as opposed to rest; conditions of feeding and varieties of food; certain curious blood changes, spontaneous, or induced by vaso-motor changes, or exposure, or the introduction of some poisonous substances not acting directly upon the kidney, any more than on any other organ (as distinguished from cantharides, turpentine, and some others); or the blood dyscrasia of malarial poisoning of mercury and of syphilis, and lastly of pregnancy. (The digestive conditions under which the diffusible proteids, produced by gastric and pancreatic digestion, appear in the urine, do not come within our present purview, and peptonuria as it is called, I shall not speak of, except to say that it is the least important of all the conditions allied to albuminuria.)

[1] The late Dr. Austin Flint in *Medical News*, December 5th, 1885, p. 638.

[2] *Op. Cit.*

At the outset I will make this general proposition, which applies to the differential diagnosis of all functional and organic diseases affecting any system or organ. For practical purposes it is incumbent upon us to show, not that the case in question is one of functional albuminuria, but that it is *not* a case of Bright's disease; in short, all possibility of the case being one of organic disease of the kidney, must be negatived before we are in a position to state, with safety, that any given case is one of functional albuminuria. I put the case thus strongly for obvious reasons. To regard a case of chronic Bright's disease as one of functional albuminuria, is to commit the gravest error in prognosis that one can possibly make, and perhaps to lay down a system of treatment absolutely injurious to the patient. While, on the other hand, to regard a case of functional albuminuria as one of Bright's disease, would be perhaps to condemn a practically healthy individual to life long invalidism and uselessness. To those who have to do with life insurance the question is one of the first importance. In making the differential diagnosis the points to be taken into consideration are as follows:—

1. *The Persistency of the Albuminuria.*—The functional forms are most commonly remittent, paroxysmal or periodic, in their manifestations; though in some cases the albuminuria is persistent. In granular kidney, too, it is said the albumen may disappear from the urine for days, or even weeks, at a time. This is a statement which ought to be received with the greatest possible caution, remembering as I said in a previous part of this lecture that you are not in a position to pronounce the absence of albumen from a given specimen of urine until it has been in contact with nitric acid for at least twenty minutes or half an hour.

(*The Quantity of Albumen is no Guide, though one may get a hint by observing it.*—As a rule, in the functional forms, it is usually marked, frequently copious, and not seldom profuse; while in the case of granular kidney it may be only small in amount. But I am quite sure that the statements made in the books in regard to the amount of albuminuria in the different varieties of chronic Bright's disease are quite unreliable.)

2. *The Quantity of Urine passed in Twenty-four Hours should also be observed.*—In the functional forms it is usually normal, while in the organic cases the quantity is seriously affected in many instances. The appearance of the urine as to colour, transparency, and deposit, is usually normal in the non-organic cases, whereas the albuminurias of renal disease usually have some appearance, which to the practised eye suggests some departure from the natural condition.

The density of the urine as a rough index of the solid material, including, of course, albumen, is of the highest value. The functional albuminurias have, of course, a practically normal urine, with albumen in solution. While those of organic disease have an abnormal urine, a urine seriously deficient in urea with albumen added to it. The former are of normal or increased specific gravity, the latter of lowered specific gravity. In cases of doubt the quantitative estimation of urea should always be performed. The examination of the urinary deposit usually shows but little in the non-dangerous forms, except crystals occasionally of oxalate of lime, and rarely tube casts. Tube casts, I may say, to be of serious import, must be in considerable quantity, of considerable size, and more or less constantly present. Of this there seems to be no doubt. Cases of acute nephritis, cases of chronic renal disease, accompanied by obvious dropsy, are scarcely likely

ever to be in question. It is the case of granular kidney, that exceedingly risky condition for operating surgeons and insurance companies, in which the diagnosis has to be made.

To make a case of functional albuminuria then, we require a practically normal urine, having in solution serum albumen. One exceedingly interesting exception to this rule concerning the urine I shall refer to; but above and beyond this we require an entire and complete absence of all the general and local conditions, which go to make up the clinical picture of Bright's disease. An absence of dropsy (with only a slight reservation for cases of anæmia), and absence of all cardiac hypertrophy as manifested by physical signs, and an absence of increased blood pressure, as evidenced mainly by slowness of the pulse, and an absence above all of the manifold conditions which indicate the uræmic state. Lastly, the occurrence of the eye changes seen in albuminuria, specially albuminuric retinitis would settle the question once for all. Still, these functional albuminurias have, or are associated with symptoms more or less their own, aud have consequently been named by various writers: cyclic, periodic, paroxysmal, dietetic, etc., the term being used to indicate the special conditions under which it makes its appearance. Dr. Moxon was one of the first in this country to draw attention to the condition, under the title of "Albuminuria of Adolescents." Perhaps no one case follows completely one special type, the same case being at one time cyclical, at another periodic or persistent. The best observed causes are exertion and feeding. As feeding is itself a cyclical performance, the albuminuria of feeding will also be cyclical in its occurrence; there is nothing very remarkable in that. That which follows the use of certain articles of diet, a rare form, will be more or less paroxysmal, according to the use of the peccant substance. I have under my care, at the present time, a young gentleman, whose case I will briefly narrate, who suffers from an exercise albuminuria. The case illustrates, in a typical manner, the leading features of the condition in question. He is nineteen years of age. Left a public school some two years ago, since when he has been occupied in the office of a large manufacturing firm. He lives in a suburb of Leeds; consequently he rises at 7; breakfasts at 7-30; walks two miles to the railway station; travels to Bradford, where he arrives soon after 9 a.m.; dines at Bradford at 1 p.m.; arrives in Leeds at 7-30, walks to his home, has tea; supper at 9; bed at 10. This is his daily round. The condition of the urine is as follows: The morning urine is always free from albumen, with exceptions to be mentioned. The urine after dinner is always albuminous, as is that passed after tea. I should say that after dinner, and after tea, urine is frequently not passed till some two or three hours after the meal. The morning urine is albuminous when the preceding day the amount of exercise has been excessive. Take his record for the last week for example: on the 6th, 7th, 8th, and 9th, the morning urine was free from albumen, but on the 10th was highly albuminous. The explanation of this is afforded by the fact that on the previous day he had been to the Exhibition at Saltaire, and so was continuously on his feet, standing and walking, from 2 p.m. to 9 p.m. On the morning of the 11th the urine was again free. Now, of course, this patient came to me for certain symptoms, not very definite in character, but which were sufficient to suggest to me the probability of my finding albumen in the urine. He himself was not inclined to make any complaint of his health, but his father sent him to me because, as he (the father) said he seemed apathetic, feeble, and unfit for work, though ill in no definite way. He is a twin-brother, tall and thin, his nose is livid, and cheeks more than high coloured. After walking to my rooms, even when the day is warm, his hands are always blue if he doesn't wear gloves, and he hates cold weather. He is very tired after slight exertion, sits over the fire, and reads rather than play tennis or cricket; takes very little food, and with no relish. There are no signs of cardiac hypertrophy. The pulse is, as you would expect, small, feeble, compressible running at 90 to 100 in the minute. The bowels are confined. In the absence of signs of Bright's disease, I have said that the albuminuria is an index only of his general condition, that it will probably disappear, and that it will not lead to or eventuate in chronic renal disease. The case is certainly a case of adolescent albuminuria, and is also cyclical in its occurrence.

The plan of treatment, which has been attended by such improvement as could be expected in the time, consists in "forced feeding;" the administration of an aloes and iron pill for constipation, and the systematic use of a mixture of hydrochloride of arsenic and perchloride of iron.

A still more striking and interesting case is also under my observation among my out-patients. A woman, æt. forty-two, has for the last twenty years suffered from giddiness, and periodic attacks of shortness of breath on exertion. She is pallid, with a slightly icteric tint, and even as she sits has a shortness of breath very similar to the nervous gasping breathing which little children have when going through their repetition of verses before strangers, sometimes stopping altogether to devote the whole of their attention to a long inspiration, after which they set off again with renewed vigour. There is no cardiac or lung lesion to explain this. She is subject also to attacks of a very remarkable character. If she walks out on a dry frosty day, without having the whole surface of the body, including the hands and face as carefully protected as possible, after a short time her face becomes pinched and ashy pale; the lips thin and tightly drawn; the eyes sunken and glazed; the shortness of breath is extreme, and, internally, painful sensations, very like the shivering of ague, pass over the whole body, leaving behind them acutely painful areas, usually on the right orbit (brow ague) or beneath the left mamma. By experience, she has found that the drinking of large quantities of warm water (on one occasion as much as three pints) soon relieve the condition, and relief is accompanied by the passage of a quantity of urine, very much like strong coffee in appearance. The micturition on these occasions being effected with pains almost as intense as those of child-birth. During the winter these attacks occur with much frequency, but as she has only recently come under my notice, I have not had an opportunity of seeing the urine in this condition. She is, like the former case, subject to dead fingers after washing, and it compelled her to do all her household work, such as cleaning, paring potatoes, etc., in warm water. She is also subject to urticarious eruptions. The black urine is clearly the urine of hæmoglobinuria.

On May 3rd, the urine was loaded with lithates as it always is; sp. gr., 1025, and highly albuminous. May 4th, after dinner, sp. gr., 1018; turbid from lithates; albumen abundant; above the disc of albumen,[1] a "second deposit;"

[1] On this exceedingly interesting appearance in the nitric acid test, see Dr. Stevens's paper in the *Edinburgh Journal*, Dec., 1886, p. 507.

pigment abundant; after tea, the same. May 5th, morning urine free from albumen; after dinner and after tea, albuminous. May 6th and 7th, the same.

In this case, the first attack occurred in 1873, now fourteen years ago, and the patient is, physically speaking, sound. The case is one of paroxysmal hæmoglobinuria, associated with cyclic or periodic albuminuria, more or less persistent. The association of functional albuminuria with paroxysmal hæmoglobinuria is one of extreme interest from a pathological and chemical point of view.

The paroxysmal attacks of hæmoglobinuria are clearly due to the dissolving out of the colouring matter of the red cells into the blood-plasma, and its escape by the kidneys. The products of the destruction of red cells, which goes on in the liver, and other organs, are disposed of in two ways, the colouring matter is worked up into bile and urinary pigments; the globulin into urea or some allied product, and so normally neither hæmoglobin nor globulin appears in the urine; but when, from some cause or other, more red cells are broken up in a given time than can be disposed of in this way, we get increase of biliary pigment, sometimes jaundice, and when the quantities are in great excess, actual hæmoglobinuria. So that functional albuminuria, or *globulinuria*, may be attended by excess of pigment in the urine, which it usually is, jaundice, as in my second case slightly, or by actual hæmoglobinuria, as has also occurred in my case. For this explanation I am indebted to a most interesting paper by Dr. Ralfe.[1]

One other point of great interest I wish also to draw your attention to:—The associations of dead fingers, and blueness and lividity of the extremities with functional albuminuria. The occurrence of dead white fingers, cold clammy feet, chilblains, etc., has long been noted in hæmoglobinuria, and recently the conditions described by Raynaud as local asphyxia, giving rise to symmetrical gangrene, have been found associated with functional albuminuria and hæmoglobinuria. This local asphyxia, or symmetrical gangrene, is no new condition, and its association with hæmoglobinuria was well known to Dr. Druitt, whose classic description of his own case is still the best account of paroxysmal hæmoglobinuria which we possess. This close association, clinically, of conditions which, pathologically, seem so far apart, is one which affords much scope for speculation. The clinical facts are not to be disputed; the pathological basis underlying them is at present involved in mystery. The suggestion that a vaso-motor spasm, or local arrest of capillary circulation, occurring at one time in the kidneys, at another in the liver, and at another the finger-tips, the nose-end, the ears, may account for all the manifestations recorded.

Hæmoglobinuria occurring for the first time excites the gravest alarm in the patient's mind, but so far as I know there is only one case of recent years which has proved fatal. The woman, whose case I have read to you, has suffered for twenty years or more, and, though very wretched at times from the curious dyspnœa, and the restricted condition as to exposure under which she is compelled to live, is, as I have said, physically sound. The cases do not end in death, or in Bright's disease. The patient may, of course, die of accident, due to local gangrene and other conditions. The treatment appears to be the same for all; such restrictions of exertion and feeding as may appear necessary from the history of the case, and the administration of the ordinary strong preparations of arsenic and iron.

[1] *British Medical Journal*, November 27th, 1886, p. 507.

QUASI-HYDROPHOBIA.

By Charles Fox, M.R.C.S.,
Cardiff.

Hydrophobia is a disease of a peculiar interest to every man and a primary one to us, mysterious as it is, baffling cure, quick, and frightful. It seems *sui generis*, it is traumatic, and in one way only, and, in consequence, every person is liable to it at any moment, well or ill, as everyone may be bitten by a dog.

But there is evidently a modification of hydrophobia, or more than one, marked by absence of the symptoms which gives it its name, and therefore incapable of classification under it. These forms of illness, though thus not hydrophobia, more resemble it than any other disease. They are connected (at least accompanied) with the same cause—a bite, and *present a peculiarity as to drinking water*. Hence, there seems to be a class of disease one might call aqua-bibitory. The common characters of such a class of maladies are undetermined as yet, and one can only state these three:—

1. Presence and probable dependence on an animal's bite.
2. Disorders of the nerves.
3. Peculiarity as to the imbibing of water:
   - (i.) Aversion—*hydrophobia*.
   - (ii.) Longing.
   - (iii.) Other peculiarities.

I shall hardly be censured probably for applying, as to the first, the inference *post hoc propter hoc*. As to the second character, there appears a wide variety, so that perhaps one might divide it into—

- (i.) Phrensied paroxysms—in hydrophobia.
- (ii.) Insensibility.
- (iii.) Moody manner and uneasiness.

In the third feature we have the two extremes present as to drinking, which seems remarkable; and it is always water that is the object of a peculiar passion in the mind. Violent aversion is well recognised, but a water-intemperance is a new notion. Thus the mysterious sign of disease after a bite (infected) seems not to be *dislike* of water, but *some* fixed feeling involuntarily present as to this element, and hydrophobia is but one and the most striking form.

Cases of these modified forms are, I suppose, not recorded, as of less moment and recoverable; but we find a hint, in V. Horsley's reference (*ex. gr.*), in a paper on hydrophobia (*British Medical Journal*, June 9th, 1888), to supposititious or non-genuine cases. These are the class he considers that Bouisson cured. And to this class belongs, doubtless, that of the French doctor himself, whose symptoms "most of" them "resembled those of hydrophobia."

In such a class of cases, what is the affection? None that is recognised. Are they to be ascribed to nervous fear, or hysteria? They could not all, if any of them, I think, be so explained. In the case that follows, the patient was somewhat strong-minded, and there was frequent insensibility.

It is proved, then, that a class of cases exist—not hydrophobia, yet analogous. I conceive they belong to the category here described, and of which the following, the only cases I have observed, are instances. They are not otherwise explained, yet they are disease.

Case 1.—E. C——, æt. seventeen, was bitten on January 21st, 1885, "of good nerve" (as I know), but delicate. The same dog had lately bitten five others; the wound was on the left hand, and half an inch long; I cauterized it

after two hours. She was under treatment nearly two weeks, the health being much affected, even to faintings, which she had "not had before." For three years was pretty well, save that at times the spot became sore, and arm had to be relieved by fotûs. But there was never an open sore. Late in January, 1888, the bite began to be painful, and numbness to be felt in it and the next fingers. The arm then swelled, until this was complete, At the infirmary amputation was spoken of, but, owing to the patient's objection only fomentations were used. No open sore. Directly it was "cured," on the evening of February 24th, recrudescent stage began. She had great movement of eyes, some garrulity, sighings, nausea, febricula, thirst, bad headaches, globus hystericus (?) affecting deglutition. 25th was first unconscious and "barked." She had been noted to have mental uneasiness, but always to be calm (as I always saw her)—not irritable, heightening of hearing and sight, no *hydrophobia*, little appetite for food, no illusions, debility, sense of obstacle in throat continually; and at the commencement of the attack she felt the site of the bite sore, and shoulder too, which feelings then left. I found it quite healed, painless, etc., with white cicatrix. After 25th, always had an exacerbation (at first always a fit) at 1 a.m. and p.m., the hour of her first, and on that day she *drank eagerly* and much. The attacks were at first almost uninterrmitted, and then have lasted for two or three hours; again, three have occurred in twenty minutes. By a week's time they had grown very irregular—four or five often coming in succession, lasting three or four minutes each, and then eight or nine hours perhaps elapsing before another. They followed no cognizable cause, and might be isolated or congregated. They were preceded by a feeling of "winding up" in the brain—as she told with her usual clearness and accuracy. They were characterised by unconsciousness, a barking noise, and sometimes also howling, which was often heard in the street, starting eagerly at things, tearing clothes, etc., *with her teeth*, and trying to *scratch* with her hands. As they varied in intensity, so did the signs. In a full attack there would be great pugnacity as well—once for two and a half hours continuously—and she would call perhaps to the (absent) dog, or sing unconsciously; the talk was not nonsensical—about her interment sometimes. It ends, I note, by a sound as of choking and *her drinking*, exhausted. She knows nothing of the fit just over, is chilly, perspiring, and calls for water. It has needed three to hold her in the fits. She would in one hold a cup of water in her hand, but *not* to take it; there was no ptyalism noticed, or change of features, but the eyes were several times closed. At first she could not be brought out of them, but after a week the rubbing of the palms, or water affusion would succeed. She told me her head was worse before and better after, but not always. The bite would be bluish before a fit. Once she woke from sleep and went into a bad fit—a new unconsciousness. At other times she was calm, and feeling nothing but headache and the glottic obstruction; there was no anxious *facies* or stiff neck, thorax, epigastrium, and respiration easy, quiet mien, no hawking. The choking was worst when emerging from a fit, and slowly lessened thence.

On March 4th, rose a few hours; first ate solids. 5th, occasionally free from choking sensation. Pulse generally 78, strong. KBr., Cinchona and Spt. æth. nit. seemed to suit. This day I applied a blister to site of bite (nearly seven hours); after five hours she had an attack for about three minutes, the first into which she subsided half awake. No special feeling at the bite, or apparent effect from the blister. I kept it open, therefore, until 11, but could not drive back the irritation to this, its source. March 7th, fits sometimes occurring in sleep. March 8th, first without "barking"; choking only felt on side of bite. The spasm of glottis in the fits caused a very loud, forcible, high-pitched sound, like "how how!" Pulse would be 114 on emergence, and fall at once to 108.

March 18th, some opisthotonos in the attacks; "stiffness," groaning on emerging; always some fits daily, mostly in evening, near together, often without "barking." Pain in left cheek, and *whole* left side affected; joints paining. Gave ac. phosph. c. pot. brom. and tinct. hyoscy., it seemed with benefit. March 21st, pain in left arm; contraction of left leg on emergence from fit; the bark not always alike. In a fit eyes might be open without her seeing, and *though insensible, she could hear a dog bark and imitate it.* April 3rd, only fifteen or twenty minutes "herself," in fits generally "awful quiet"; *better before and worse after* than formerly; less frequent. April 5th, remarkable somnambulism (never before). Great family trials and disturbances. April 23rd, been up two weeks and working when I called; fits always at least once daily, but much milder. April 25th, last "bark," two months after the first. At end of month fits ceased—*i.e.*, three months from the affection of the arm, and three years and three months from the date of the bite.

Case 2.—Was called to a woman in strange frenzies, apparently of gastric origin, as she suffered much in the stomach. It is probable in her case it was from "drink." Very eager longing for water, and took it almost clutching the vessel, and with a noise. I found, on enquiry, she had been bitten a few days before on the hand—no soreness, etc.—I think by a cat. Not cauterized. Middle-aged. Well next day. Strong person.

Case 3.—A girl I saw at London Hospital, in 1870, æt. sixteen, bitten by a lap-dog eight days before, and well since. Very small bite on left wrist. Cauterized, and she became feverish and flurried. I noted increase of temperature, decrease of temper, watchfulness, restlessness, speaking gravely and slowly on trivial subjects of little pertinency, but not "wandering," long talks, and melancholy. No difficulty in drinking, but expressed to me *a wish to have only cold water.* J. Hutchinson, as I also noted, thought this not hydrophobia, but evidently an incipient phase, say of typhoid. N.B.—Here there were no "barking" or fits, and I found she had been in service (hard), and rather strange in mind.

Case 4.—A police case has just come to notice of a large, strong man, at Newport, "thirsting" (as he said) "for blood," attempting suicide, and very excited. Five constables had to hold him, and it is believed he has drowned himself, having escaped. The only cause we hear of is that he was bitten by a dog a month ago on the nose, and hence he barked in his frenzied states—though this is not supposed to be the cause. I think it to be.

Case 5.—This illustrates the supervention of alarming illness upon the healing of a local ulcer. E. C——, a butcher had had obstinate, bad ulcers, and was cured of them by a "quack" at once, after sixteen years. He very soon died, hydrophobic.

Case 6.—J. F——, always a strong man, breaking his leg, received a wound in the heel from an iron in the cradle it hung in. After being tortured long, he was relieved by his wife, and the surgeon found it mortifying.

It discharged for six months. Directly it dried he began to feel a choking, which went on until in eighteen months he died of some growth in the throat, æt. sixty-four.

There are some very interesting features in Case 1 in respect to Heredity. The old father (of *odd* mind, and whose father was insane) was bitten when in petticoats on the ear, and a younger brother has also been bitten. I know a family, also, in which father, mother, son, and daughter, were or are all uncommon subjects of perils and fearful escapes, and the family consisted of these four. In all but the son they were generally by horses. Here many will see coincidence; but "coincidences" are *really* explicable, being accounted such from our ignorance of some field of causation. Since there is no chance, there must be *some* law in everything, making it befall as it does. So, as I have known hernia to be hereditary sometimes, here the other "accident" of being bitten seems so. To regard it physiologically, there are states of blood or temperament selected by fleas; the same may explain an obnoxiousness to mad dogs, or other contingencies. Such a theory would find support in the fact known to me of both father aud son losing their lives at different times by horses, being doctors who drove. We know little of occult laws and deeper causes, which may descend. The case of E. C—— also illustrates the law of Periodicity, which we are finding now to have a wide application or sphere. The father feels the spot sore at the season he was bitten even yet, and the teeth-marks are then to be seen. He has been in bed two days from the malaise caused. In E. C—— herself we saw that the attacks at first observed, every revolution, the hour at which they began.

AN ENQUIRY INTO THE CURRENT THEORIES OF THE CAUSES AND NATURE OF ACUTE RHEUMATISM, AND THE TREATMENT GENERALLY ADOPTED FOR ITS CURE.

By Alexander Harkin, M.D., F.R.C.S.,

consulting physician mater infirmorum hospital, belfast.

(*Continued from p.* 21.)

TREATMENT.

The subject of treatment now demands our attention, and presents itself under a variety of aspects and conditions; truly there is not another member of the nosological series for which a greater number, or more diverse remedies have been assigned, or with more variable success. Every curative agent, whether topical or general, suggested by its physiological action on the system, in the round of scientific therapeutics has been tried, and even outside the circle of rational medicine the aid of utilitarian empiricism has been invoked in the search for a reliable specific for acute rheumatism. Nihilism has countered with polypharmacy in indecisive combat, acids and alkalies, venesection and quinine, mercury and mint water, hot blankets and the cold pack, cotton wool and ice-bags to the joints and spine, opium and atropine, hypodermic injection of cold water and of carbolic acid into the affected joints, aconite and veratrum viride, subcutaneous injection of morphia and the peripheral blistering of Davies and Dechilly, and finally, the most fashionable, though least reliable of all, salicine, salicylic acid, and its compounds, have each had their enthusiastic advocates; and after all, the statement of Fuller is as applicable as when he announced, more than a quarter of a century ago, "that each and every plan of treatment which has hitherto been proposed, is regarded by the profession as unsatisfactory," and that of Garrod is equally well founded—viz., "that further observation and experiment are required before we can arrive at any satisfactory conclusion with regard to its pathology."[1] Senator also declares "that no remedy has, up to the present time, established its claim to universal favour, none has been discovered to possess undoubtedly specific virtues, to be capable of summarily arresting the disease under all circumstances."[2] Of this heterogeneous mass of remedies and *pseudo* specifics, it will suffice for my present purpose to review the expectant plan of Gull and Sutton, the joint blistering, the alkaline, and the salicylic or palliative methods of procedure.

Sir William Gull would seem in practice, if not in express terms, to have classified rheumatic fever as a specific form of continued fever, marked by a stage of growth, maturity, and decline, looking on as in typhus or typhoid for a natural termination at a determinate period, by crisis or lysis, trusting solely to the *vis medicatrix naturæ*, and not attempting by medical agency to interfere with or shorten the course of the disease. While doubtless the moderate success of the *laisser faire* treatment has enabled Sir W. Gull to fulminate an emphatic protest against the perils of meddlesome polypharmacy, he has not succeeded in commending his peculiar procedure to public acceptance: the result of his experiments has shown that (as compared with the alternative plans of lemon juice or alkalies) its effect, whether in the acute stage, or on the malady as a whole, has been to prolong its duration; while it has no more favourable results to show in the prevention of cardiac affections, the acute stage, according to Gull and Sutton, lasting under their plan for 9·1 days, 8·4 under the blistering, 6·73 under alkaline, and only 6·8 days under lemon juice treatment, the total length of the attack under alkalies being 13·5 days, when otherwise treated 19 days, the cases left entirely without medical treatment lasting longer than any of the rest. Sir William Gull's late remarkable denunciation of pharmaceutical remedies, and his advice in the treatment of disease, "to throw physic to the dogs," and trust to blankets and rest in bed, is hardly justified by his limited success in the cure of rheumatic fever. Consequent on the acceptance of the *materies morbi* and lactic acid hypothesis, and suggestive of an eliminative or evacuant method of treatment, the joint blistering plan of Dechilly and Davies, foreshadowed by Todd, was recently much in vogue, and may possibly still have some adherents. Davies insisted that the rheumatic poison was especially plentiful in the vicinity of the affected joints, and that by his treatment it was separated with the serum of the blister, and thus removed from the system. But apart from its want of success, the application of cantharidian plaisters over a multiplicity of joints was very objectionable, and not without danger of inducing strangury and even cystitis, and the slight corresponding improvement was not found in practice to compensate for the burning pain and discomfort superinduced immediately over or in the immediate neighbourhood of the inflamed synovial and fibrous membranes, ligaments, and joints.

Gull and Sutton, as reported in the *Medico-Chirurgical Transactions*, state that any more than lemon juice or alkalies, blisters do not shorten the course of the rheumatic

[1] Reynolds, vol. 2, p. 904.

[2] Ziemsen, vol. xvi., Art.—*Polyarthritis Rheumatica Acuta.*

fever, and though they may lessen the pain, they do not prevent the occurrence of heart disease; and Senator testifies "that having seen the blistering treatment repeatedly carried out in the wards of the Berlin Charité, without any result beyond a slight and only temporary diminution of articular swelling, and transient fall of temperature; he never saw the blistering cause any change in the state of the urine, and the other effects were not more brilliant than those produced by other modes of treatment. The simultaneous application of a number of blisters is not without its drawbacks; strangury is not a very uncommon result, and the urinary irritation may even be intense enough to culminate in a fibrous inflammation."[1] J. Mitchell Bruce writes, "that although the blistering plan of Davies relieves pain, statistics show that other methods of treatment are more efficacious in shaping the course of the disease and lessening the tendency to cardiac complications. On the other hand the danger of strangury, sloughing, and even pyemia, and the substitution of another severe form of pain for that dispelled, must be mentioned as objections to its employment." And Bristowe likewise protests that, "while blisters give immediate and marvellous relief to the pain of the inflamed joints, they do not cut short the progress of the inflammation which they relieve, and have no influence whatever on the general progress of the rheumatic attack." And as a matter of fact, the assumption upon which this eliminant plan of treatment is propounded is absolutely without foundation, as I have often demonstrated, and as anyone can satisfy himself, that neither acid nor any other abnormal product is discoverable in the blister serum of rheumatic patients, whether obtained from the articular or cardiac regions; and even Senator, writing on this point, declares that "this plan failed to render the urine alkaline, and that if any poison was thereby removed from the system, it was not an acid, as the serum produced by vesication was invariably alkaline."

Since the days of Furnival and Prout, nearly fifty years ago, until the introduction of the present routine treatment of acute rheumatism, the alkaline, or, more properly, the saline method of treatment, had held sway, and dominated over the other therapeutic plans; based upon the central idea of the alkali potassium, the salts of potash, such as the bicarbonate, acetate, citrate, nitrate, iodide, bromide, and tartrate have been administered, separately and in combination, and with results, as we are informed, satisfactory to the prescribers. Liquor potassæ in half drachm doses, to the extent of six drachms daily, has been given by Parkes, Brocklesby has given 10 drachms of the nitrate dissolved in water gruel, in twenty-four hours, with advantage, and when the strictly saline formula is adopted, a solution of the combined salts of the bicarbonate, nitrate, and acetate of potash is given in such doses that 12 drachms of the mixed salts may often be taken in one day; the leading idea being to introduce into the system as rapidly and as effectually as possible, large doses of any salt, of which potassium forms the base. The same principle appears to actuate Dr. Austin Flint in ordering baths saturated with the salts of potash for his rheumatic patients. Evidence as to the curative efficacy of the saline treatment is somewhat contradictory; Sir Thomas Watson states that alkalies prolong convalescence, and Gull and Sutton, while not challenging the statement that alkalies and blisters may relieve pain, deny that they shorten the disorder, or prevent the occurrence of heart disease. Bartholow says "that alkalies cannot oxidise uric acid in the blood, their administration makes the urine neutral, or alkaline with uric acid diminished and urea correspondingly increased." On the other hand, Roberts in his "Theory and Practice of Medicine" states that "a tolerably extensive experience has convinced me that good results frequently follow the alkaline treatment. Whether the treatment shortens the course of the disease or not it is impossible to say, but it certainly appears to exercise a beneficial effect on the joint affection, and my belief is that alkalies are decidedly useful in preventing and relieving the cardiac complication; the bicarbonate of potash is the preparation I usually employ."[1] J. Mitchell Bruce, in Quain's "Dictionary of Medicine," announces his belief that in alkalies a direct antidote exists to the morbid influence, but that the greatest care must be taken lest their exhibition should be overdone.[2] Furnival, quoted by Senator, treated fifty cases by alkalies without the heart being implicated in one of them. Dickinson, too, had but one case of heart disease among forty-eight patients thus treated, and thirty-five in 113 treated otherwise; Fuller in nine only out of 417 cases under alkaline treatment. According to Aitkin the alkalies should be given largely, and in justification of this advice and the liberal administration of alkalies and salines, he quotes Stevens, who states that it has now been abundantly demonstrated that in cases of acute rheumatism there is an absolute deficiency of the saline ingredients of the blood; and while there is also a liability to fibrinous exudation, the tendency of saline remedies is to suspend the separation of fibrine.

This recommendation to push the salines reminds one of Sir Thomas Watson's witty remark in reference to the liberal intra-venous injection of salines in Asiatic cholera: "Certain practitioners maintained," he said, "that the disease was to be remedied by introducing into the system a large quantity of neutral salts, which were to liquefy the blood and restore the function of the circulation. But of this practice it was said, that however it might be with pigs or herrings, *salting* a patient was not always the same thing as curing him."[3] However, undoubtedly the balance of testimony is in favour of some important advantages being derived from the alkaline or saline treatment; and when its advocates can boast that the patients lose their pains under its influence, and proceed rapidly to convalescence; that the pulse is generally tranquillised within forty-eight hours from the commencement of treatment; that its good effects in warding off cardiac affections are certified to by such eminent authorities as Fuller, Garrod, Basham, and Goodfellow, as well as the shortening of the illness,[4] one might be pardoned if he expressed his wonder that with such a favourable record, and with a plausible hypothesis to encourage them, they should vail their flags in presence of the apostles of a new dispensation, who with every evidence of the co-existence of organic disease in the majority of cases, only take cognizance of functional or subjective troubles; who ring the changes on pain and pyrexia, pyrexia and pain; whose main dependence is an empirical drug, the product of the laboratory, a so-called specific; and while taking credit through its agency in relieving pain and fever, openly acknowledge that the drug has no influence whatever in preventing or relieving heart

affections, the principal source of danger in rheumatism; that it retards recovery, and predisposes to relapses; that it leaves its victims weak and anæmic; that it is powerless in the prevention or cure of hyper-pyrexia; and that its administration, even under the most careful supervision, is followed too frequently by most lamentable results—syncope, delirium, and death itself.

The palliative plan of treatment by salicine and the salicylates, now on the wane, has enjoyed for more than a decade the distinction of being the fashionable remedy, and has during that time left a very diversified record of its operations. Never rising to the dignity of a curative measure, it has addressed itself to the humbler *rôle* of treating symptoms; and while pleasing the patient by soothing and lessening his feelings of discomfort in those organs in which pain and inflammation go hand in hand, has minimised or overlooked the importance of inflammation in the vital organs, where pain is merely of incidental occurrence, and from injury to which a fatal result is only to be feared. As Sieveking very properly observes: "Even the tyro in medicine can scarcely help being struck by the circumstances observable after a very brief clinical study, that pain and danger are by no means commensurate. They often appear to occupy an inverse ratio to one another. Many of the most fatal diseases run their course almost without pain; while, on the other hand, long-continued suffering may stretch the patient on the rack without materially abridging life. Our daily experience shows us how, but for the indications afforded by the stethoscope and other means of objective examination, the localisation of disease is impossible, and the patient has no subjective symptoms to adduce but that of general malaise and weakness. There is a marked difference, for instance, between endocarditis and pericarditis (and he might have added, arthritis) in the relative amount of pain which each entails, inflammation of the pericardium ordinarily causing the patient to draw the physician's attention to the part; while, as a rule, the stethoscope alone can detect the inflammation that affects the lining membrane of the heart. What a practical demonstration is this of the advantages of a thoroughly scientific education, that shall lead the medical man to depend upon himself rather than to be guided by the mere symptomatology which shall be indicated by the patient's feelings."[1]

After being experimented with in Germany the salicyl treatment was introduced into this country by Dr. Maclagan, who then assured us "that it seems to arrest the course of the malady as effectually as quinine cures an ague, or ipecacuanha a dysentery; that, given sufficiently early, and in sufficient doses, it prevents cardiac complications, and that its free administration is the best means of staying their progress after they have occurred." With this assurance, and its evident power over pain, it became almost universally prescribed in acute rheumatism. The contrast is remarkable when we compare the opinion of the same authority, founded on six years of practical experience of the drug, on the occasion of a discussion on the salicyl treatment, by the leading physicians of the metropolis, at a meeting of the Royal Medical Society on December 19th, 1881: "Practically," Dr. Maclagan says, "we have to deal only with salicine and salicylic acid (generally given as salicylate of soda). Salicylate of soda is most used, but no one who has used it much can have failed to notice its deleterious effects on the system. Many instances have been recorded, and their number has been swelled in almost every journal that we read, in which more or less disastrous effects have been produced by it—delirium, insanity, prostration of the vital powers, syncope, and even death. Salicine is equally powerful as an anti-rheumatic, but it produces none of the deleterious effects of the salicylates. Whether or not the salicyl treatment of acute rheumatism diminishes the frequency and danger of heart complications is a point on which I have not time to enter. I believe that to some extent it does, but I believe also that when these occur the treatment by salicylates of soda occasionally increases the patient's danger. I refer more especially to those cases, more numerous than is usually supposed, in which the muscular substance of the heart is the seat of inflammation; if to this enfeeblement is added the administration of salicylate of soda, the patient's condition is thereby rendered more serious, and the continued administration of the salicylates might turn the scale against him. Hyperpyrexia is no essential part of the rheumatic process. All evidence shows that it is not at all benefited by the salicyl compounds; they are quite inoperative in it." What a difference between the two pronouncements! Dr. Maclagan's admissions are, however, very creditable to his candour. The risk attending the use of the salicyl compounds has been generally recognised by his professional brethren; but the differentiation which he would wish to establish between the effects of salicine and the salicyl salts has not been as well received. One good result has come of this very necessary caution—the remedy is not now so promiscuously prescribed, and its effects on the heart and nervous system are more narrowly watched.

There is, too, a great divergence of opinion regarding the method of administration, arising from opposing views of the etiology of acute rheumatism. Dr. Maclagan, believing in the malarial origin, and regarding the rheumatic virus as a veritable entity, prescribes the drug as an antidote, for the avowed purpose of destroying the poison, and deprecates the production of the constitutional, the toxic effects on the nervous system; while his most prominent follower, Professor Latham, from the *materies morbi*, the uric acid point of causation, gives distinctly opposite advice. In rule 3 of his code he directs: "Place the patient freely under the influence of the drug, that is, let him have sufficient to produce cerebral disturbance, *i.e.*, buzzing in the ears, or headache, or slight deafness; with the development of these symptoms the temperature and the pain will begin to decline, but, as soon as the formation of the *materies morbi* is stopped, its peculiar physiological effects are developed. Acting as an antidote, the greater the amount of the poison, the larger must be the amount of the remedy. He concedes, however, that if pericarditis, endocarditis, pneumonia, or pleurisy have been developed the remedy is powerless. Its use requires caution. You cannot tell when the system is saturated with the remedy, and you must therefore trust to smaller doses and other remedies for controlling the disease."[1]

During the important discussion referred to previously the majority of the speakers appeared to attach importance to the salicylates, and the conclusions formulated by Dr. Sydney Coupland may be taken as embodying those of the members present. The most important of these conclusions are: 1. That in the majority of cases salicylate of soda speedily reduces the pyrexia and articular pain of acute rheumatism.

[1] *British Medical Journal*, February 9th, 1867. Sieveking on "The Etiology of Pain."

[1] Croonian Lectures, 1886.

2. That no definite influence on the cardiac or other complications can be observed, and that, indeed, both pericarditis and endocarditis may develop while the patient is under its influence. 3. That the toxic effects are serious according to the largeness of the dose.

The contribution to the discussion by Dr. J. Gilbert Smith, of the London Hospital, is worthy of the highest consideration. He admits that ample proof has been adduced by previous speakers of the power of the drug to reduce pain and temperature, and arthritic inflammation, but it has not been shown, he continues, that the stay in bed has been materially shortened, or convalescence hastened, and relapse, in place of being prevented, is more frequent. He asks the pertinent question: "So long, then, as these latter points remain as they are we may ask, Do the salicylic compounds *cure* rheumatic fever, or do they merely prevent certain of the manifestations, arresting them as opium does pain, while the disease itself, or its specific virus, remains in readiness to demonstrate its activity on the first opportunity?" His next query: "Is there any evidence afforded by hospital statistics to show that the cardiac complications of rheumatism have been in any way affected by the introduction of the salicines? The importance of the question," he says, "is apparent, seeing that the chief element of danger, present and future, is imparted to it by the great liability that exists to inflammatory processes in and around the heart. And, if as affirmed, the salicyl compounds actually *cure* rheumatic fever, we may then reasonably expect that the occurrence of cardiac complications may be mitigated, if not altogether prevented, or, if such has actually taken place, that its progress may be showed and its perils abated and arrested." And Dr. Fagge, also, in his valuable remarks, expressed in equally strong terms a similar expectation of its being likely, naturally, to control the development of an analogous process in the heart.

With a view of elucidating these doubtful questions, Dr. Gilbert Smith prepared a number of tables of hospital statistics of cases treated in the principal London hospitals in reference to the incidence of heart complication in the pre-salicylic era, as well as of similar cases of acute rheumatism treated subsequent to its introduction.

Table I. presents a classical series of cases treated in the years between 1876 and 1882, in all, amounting to 1727, of which 940, or from fifty-two to fifty-four per cent., were so affected. Table II. gives the number of cardiac attacks *subsequent* to the introduction of the salicyl treatment, which comprised 1748, of whom 1109, or sixty-three to sixty-four per cent. presented heart complication, or against fifty-four or fifty-four to sixty in the previous table. Table III. shows the amount of cardiac complications in primary attacks, and out of 629, 381, or sixty per cent. were so affected. Table IV. gives similar statistics of 533 cases treated by the salicylic compounds alone, and it also exhibits the highest percentage of cardiac complications—viz., sixty per cent. From the consideration of these tables, Dr. Gilbert Smith says, in conclusion, "That, notwithstanding, our expectations based on the good effect of the salicyl compounds in several of the marked features of rheumatic fever, there is no evidence, so far as hospital statistics are concerned, to show that the introduction of the salicylic treatment has led to diminution in the amount of cardiac complications in acute rheumatism."[1] The contrast is very striking when we compare, with these tabular returns, the statistics of Dr. Dickinson, showing the power of alkalies in preventing and controlling the occurrence of heart affections in the same disease.

Coming to a more recent date, we must not forget that Dr. W. H. Broadbent, from the presidential chair of the Clinical Society of London, at its meeting in January, 1887, considered that it was his duty to raise a warning voice against the promiscuous or routine administration of antipyretics, especially of the salicylates, salicine, salicylic acid, and its compounds, and the danger accruing of present injury from their employment. It is a tremendous piece of knowledge, he said, that a given drug will certainly lower the temperature, but this does not by any means warrant its indiscriminate administration in pyrexia. There is the further question, by what process the temperature is reduced, and what concomitant effects are produced? There is positive peril in acting simply on the knowledge that the temperature can be lowered. Are we certain, to begin with, that a high temperature is always mischievous? May we not, in checking it, be interfering with defensive or readjusting processes? Are we to assume that nature does not know what she is about, when she sets the heat regulating mechanism for a higher level whenever things go wrong in the economy? Even with the employment of salicine and salicylates in rheumatism—remedies which come straight to us from the laboratory, and whose mode of action is expounded in chemical formulæ by Dr. Latham—I think it will be well to raise a warning note. Properly employed salicine and the salicylates almost rob acute rheumatism of its terrors and dangers, but, given in routine fashion as we should give an effervescing mixture, they have seemed to me to be capable of doing serious harm. At any rate, I have seen deaths in rheumatic fever of a kind quite new and strange to me, after prolonged administration of salicylate of soda every four and six hours. The pain and fever had never yielded; the drug had been continued in hope of this result, till, in course of time, warning was given by delirium; the pulse became more frequent and extremely weak. What has looked like a modified hyper-pyrexia has set in, with flushed face, and hot perspiring skin, and the patient has rapidly sunk, the temperature, however, never rising above 105 Fahr. I come back then to my point, that in order that we may employ antipyretics, or remedies, of any kind with confidence, we must know exactly how the effects produced are brought about; the chemical changes which attend and condition the evolution of nerve force and muscular action; the modification of the clinical processes which result from the administration of the drug; and the change in the composition of the drug itself, through which the energy is evolved by means of which it produced its effects.[1]

Coming to a still later period, April, 1888, Dr. Hood's contribution, entitled, "The Treatment of Acute Rheumatism," with special reference to the use of salicylates, and read before the Royal Medical Society of London, bring up the consideration of the subject almost to the present day. The paper is important, both from the number of patients treated in two of the largest metropolitan hospitals (Guy's and Bartholomew's), and from the nature of the conclusions arrived at, after due consideration, the dose in almost every instance being uniform—viz., twenty grains of salicylate of soda, every one, two, or more hours. The effect on the joints was, that in many cases patients experienced a

[1] *Vide Lancet*, January 28th, 1882, p. 187.

[1] Dr. Broadbent, *Lancet*, January 28th, 1882, p. 138.

marked and rapid or total cessation of pain, with equally rapid fall of temperature; of 728, 528 lost their pains in five days, but with a heavy list of 137 relapses; out of 515 in St. Bartholomew's, 300 were completely relieved in three days, with forty per cent. of relapses. The illness following relapse being of a more intense character, and higher temperature than in the initial attack, and in most cases combined with cardiac mischief. As to the frequency of cardiac lesions, considering the cases in aggregate, slightly over sixty per cent. were affected; while of the cases treated without this drug, slightly under sixty per cent. were affected. Practically, these percentages confirm the impression that the salicylates have no effect whatever in either reducing or limiting the intensity of the cardiac inflammation occurring during the course of acute rheumatism. The author stated from his own study of the matter, that dangerous symptoms occurred in many cases when the temperature had fallen to normal, and the pain had completely subsided. In these cases, furious delirium ushered in hyper-pyrexia, with fatal results—nine cases of such being detailed. As a proof that the drug had been given in these cases in sufficient quantity, he stated that in one, fifty grains of salicine had been given every hour; in another, twenty grains of salicylate of soda every hour for two days, with relief of pain and fever, and yet hyper-pyrexia occurred when under these large doses. Again, this alarming symptom disappeared in other cases when the dangerous drug was discontinued. In some cases, even when given in very small doses, toxic results occurred, having produced a grave state of cardiac depression.

Patients treated thus are peculiarly liable to delirium; while, according to Senator, acute rheumatism is rarely complicated even with mild forms of delirium. A careful study of a large number of cases could not in any way support the view that in salicylates were to be found specifics for acute rheumatism. If specifics, they should have an antagonistic influence over the complications, as well as the pain. Endocarditis, pericarditis, and pleurisy, are as much the results of the disease as swollen and painful joints, and as such should be directly influenced by the remedy, but such is not the case: these complications appear when the patient is under the influence of the salicylates. He considers that in sthenic attacks salicylates may directly benefit the patient; in subacute attacks they may act as anodynes with tonic and general treatment; in the nervous class, with tendency to delirium, they should be given with great caution, and are often highly dangerous. When the attack is complicated with the severe forms of cardiac or pulmonary inflammation, it is advisable to discontinue their use.[1]

I shall conclude by a reference to an article contained in "The System of Practical Medicine," by American authors, vol. ii., written by Dr. R. Palmer Howard, of McGill University, Montreal, and I shall adopt the words of the reviewer in the *International Journal of the Medical Sciences*, January, 1886: "In the section on treatment the use of the salicylates is discussed at length, and the author's conclusions may be thus summarised: The articular pain and the fever are more or less speedily removed, relapses are more frequent—probably much more frequent under this than the old modes; the salicyl compounds do not arrest or control the rheumatic inflammation of the endo- or pericardium, though on this point therapeutists are divided. Hyper-pyrexia is not always prevented; the average duration of the disease is not very materially lessened; indeed, there is some evidence that the salicylate treatment actually prolongs the time spent in hospital. And, lastly, there are often serious effects from the use of the drug. In reading this careful analysis, in the preparation of which the whole range of medical literature has been laid under contribution, we confess to a feeling of sadness—'another therapeutic dream dispelled;' and ten years ago we were full of hope that in the salicylates a specific had been secured. However, we are daily gaining information as to the cases in which the salicylates are really valuable, and ascertaining the causes of failure.

OBSTRUCTION TO NATURAL LABOUR BY THE TWISTING OF FUNIS ROUND THE NECK OF THE CHILD.

By Thomas M. Dolan, M.D.

Tardy labour caused by this complication is, I believe, more frequent than is generally imagined. In our text-books and general treatises this cause of protracted labour is generally only cursorily alluded to. Though we have an excellent paper contributed to the Obstetrical Society by Dr. Matthew Duncan, "On Shortness of the Cord as the cause of Obstruction," my notes may serve the useful purpose of confirming his evidence, and may help some junior practitioners by again directing their attention to this cause of delay.

Fig I

My attention was drawn to the subject in 1865 by an old and experienced general practitioner, and since then I have had repeated occasions of verifying the prognosis, that the cord was twisted round the neck of the child (fig 1 and 2); hence the delay in the determination of the labour. The class of case in which a prognosis can be formed may be briefly described. Natural labour progresses favourably until the head is brought well down. We have every reason to believe that a speedy termination will take place. The presentation is natural; the pelvis roomy; there is no

obstruction; the maternal passages are in a soft dilatable condition. The pains continue, but progress is slow. Hours may elapse without termination of the labour. Then a more violent pain comes on; the child is expelled, its expulsion being followed by a free discharge of blood. The

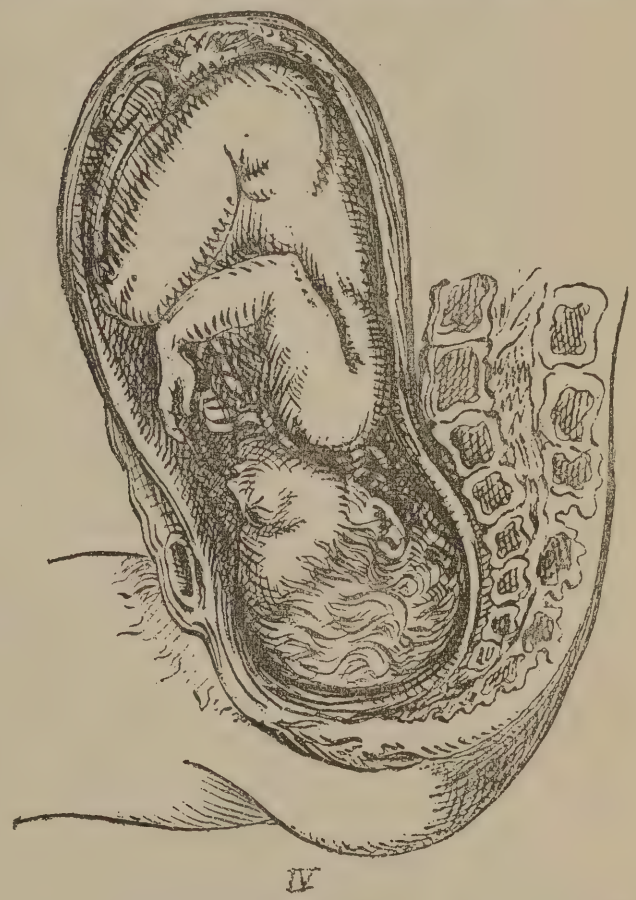
FIG. II.

cord is found twisted tightly round neck of child. Some trouble will have to be undergone to overcome asphyxia of child. The mechanism is simple. The tension of cord has kept the child back; the resistance at first has not been

FIG. III.

sufficient to separate placenta; but this at length in the class of case I am describing does take place. At last the child is expelled, and we have a gush of blood following on the partial separation of the placenta.

The degree of stretching a cord will undergo depends very much on thickness of cord. The degree of strain will also depend on many conditions, such as position of placenta. With a long cord and placenta attached to fundus, as in fig. 3 and 4, a slight degree of tension of cord would keep the head for a long time in one position; labour would be slow. Sometimes the cord is coiled round the neck; but so long that the head may be born; here there is danger of asphyxia, and it may become necessary to cut the cord, taking due precautions against loss of blood.



IV

If we look at the drawings we shall see that if the placenta be attached to the fundus, the child will be swung, and that in proportion to the strain, so will be the gradual tightening. The question might be put in mathematical form; but owing to the uncertainty of one factor, it cannot be solved. The question is the amount of pressure necessary to overcome resistance caused by twisting of cord round the neck, with placenta in the fundus position, and the measure estimated in foot pounds. We can estimate tolerably accurately the pressure of a labour pain, but the difficulty is as to the stretching power of the funis. Experiments on the cord after birth are not of value, because we are dealing with dead matter; and in this dead state we can stretch it by a gradual application of weights until we reach the breaking point. This varies very much even in the dead cord. This is only of theoretical interest. The practical points are:

1. *Diagnosis.*—This, I believe, can be readily made.
2. *Treatment.*—The natural pains are generally sufficient

to overcome the obstruction, if time be allowed, but help can be afforded by the application of a firm binder, or manual application to the fundus. In some cases the forceps may be required, as it is to be remembered that the child's life is in jeopardy owing to the contingency of long-continued pressure.

NEURASTHENIA—TRUE AND FALSE.

DIAGNOSIS AND MANAGEMENT.

By Andrew Scott Myrtle, M.D.

Every one who, like myself, has been in regular practice during the past forty years, cannot have failed to have marked the steady, ever-growing number of neurotic patients demanding our attention. This evolution constitutes one of the most striking among the many changes in the types of disease which have taken place during this most eventful period. Not only has there been a great increase in the number of this class, but the symptoms have become more and more urgent, varied, and complicated, often proving beyond our comprehension and control, and sometimes passing from mere functional disorders to organic changes of vital consequence, notwithstanding the amount of light which scientists have recently thrown on all nervous affections, whether central or peripheral. In evidence of the growing importance of this class of patients, permit me to direct your attention to some remarks made by my old friend, Sir James Crichton Browne, when he presided at the second anniversary of the Neurological Society, not quite a year ago. After showing that increase of knowledge—civilisation, in fact—led to a division of labour, and *that* to specialism in every vocation, he said "that the diseases of the nervous system—which were certainly very complex, very obscure, and very varied; which required to be investigated by special methods and special instruments, and which had, constantly, light thrown on them by physiology on the one hand, and psychology on the other—constituted a natural and real speciality in medicine, which might well demand the undivided attention of a group of physicians." He further added "that the nervous temperament was in the ascendant," and predicted that "nervous diseases shall be the diseases of the future," by which I understand him to mean, not that these shall be the only diseases that the coming race shall suffer from, but that we practitioners of to-day, and especially those coming after us, must take into consideration the influence of the nervous system, and in dealing with disease, whenever found, or in whatever structure, make due allowance for that influence. The best proof of the rapid growth of health derangements having this as a factor is to be found not in the words of our distinguished associate, but in the fact that a Neurological Society has been formed, and numbers among its ranks some of the leading minds of the day. On this account I felt inclined to read the following remarks at one of their meetings, but on second thoughts I determined to bring the matter before this great representative gathering, and so procure a general hearing as well as the experience of the rank and file of, as I may term it, the profession.[1]

The term Neurasthenia is, I think, nosologically correct, and defines the actual condition of its subject. It has been accepted, for long, by us with one dissentient, as far as I know, and the term neuro-kinesis, suggested by the late Dr. de Bert Howell, would be no improvement for the best of all reasons. "Shock," as I understand it, and as far as my experience goes, is a most unusual cause of this form of breakdown; for as the stone is frittered away by the constant drop dropping, not by the sudden gush, so neurasthenia is, in the great majority of cases, the result of a slow, silent, ever present worry, often introspective, known as well as felt by its victim only. As I reject shock as a common cause of true neurasthenia, I also reject hysteria; whilst I admit that hysterical bursts are sometimes seen, they are neither frequent nor characteristic. The true neurasthenic often showing a marvellous power in suppressing all emotional manifestations, and bearing the heavy burden of her own incapacity in a spirit of resignation, and without complaint, making one, again and again, wonder at the magnaminity displayed by such frail creatures, as well as at the purity of their minds and gentleness of their ways; and it is with the greatest pleasure that I now bear witness to the fact that among *them*, I cannot recall a single case where the lower nature, the sexual, has had any place or power in the production of this form of nerve failure.

The loss of power such as I now speak of comes on gradually—does not observe any regular course. In its approach it is often unheeded by patient, friends and medical attendant. The ordinary duties of life are followed; the fulfilment of such, however, becomes, each day, more and more difficult. Mind and body go hand in hand in their downward career, and at the end of weeks, months, it may be years, and after a gallant struggle, both show signs of distress. Muscular efforts become more and more forced and painful. The special senses become more and more intolerant; light offends; sounds, the slightest, disconcert. Sometimes the merest touch is resented, the mind less and less capable, the patient soon ceases to take an interest in the world outside, and longs for solitude and rest. With all these we may have vague flying, or severe localised neuralgic pains, yet no apparent interruption in the performance of the various functions. The body may be as well nourished. Food with stimulants and tonics may be given, and taken abundantly, still strength does not return. Somehow the main spring of life has lost all power—has become bankrupt and can no longer supply the vital force necessary for active existence. On enquiry you will generally find that this condition has been preceded by one of heavy and uninterrupted responsibility—watching night and day by the sick bed, anxiety, worry, domestic troubles and bereavement. The prostration is not only complete, but continued. We have no glimpse of sunshine here; never find the patient able to do a good deal one day, and nothing for a month. We may find she suffers much less one day than another, but we never find that she can do much more, and if by advice of injudicious friends, or of her own accord, this is attempted, the result is disappointment and suffering. Sickness often persistent, intense pain in head or spine, general irritability with febrile symptoms, sleeplessness, palpitation, and often what is worst of all, the fidgets. We have no sham illness to deal with here, but one of the most difficult clinical problems to solve. The late Dr. Jephson, of Leamington, made more than one serious mistake in attempting this. With all his knowledge of human nature, all his experience of faddy fashionable women, he failed to realise, that without any visible sign of disease—nay, in one whose face and figure, whose outer shell, in fact, showed neither flaw

[1] This paper was written for the meeting of the British Medical Association last year, and was among those "taken as read."

nor crack, the strings of the instrument which should have given it, all its power and sweetness had snapped—and left the body as incapable as a locomotive without steam. If you study such a patient you will find her most anxious, most willing to do, and take everything you recommend; showing such faith in your plan, that she will try and do more than you have asked her, fancying thereby to advance all the more rapidly towards recovery. You will find her exhibiting a certain amount of unselfishness and consideration for others, and whilst most grateful for kindness, often showing a sense of heartfelt regret at the trouble and expense her condition necessarily entails. These, I think, you must admit are strong proofs of her own honesty of purpose, and that here we have no perversion of the ego, but a total collapse.

I now come to what I call False Neurasthenia. Here we find symptoms, in every respect, similar to those of true, and it will take you all your time and patience, as well as tact, to detect the sham from the real. If you hark back a bit, you will find that as a child she showed temper; was wayward; as she grew, she became fitful, hysterical, and given to the sulks; craved for sympathy, and exhibited little or no sympathy for others. On questioning her, she describes her sufferings in forcible language. She can neither eat nor sleep; has not an atom of strength; suffers from the most dreadful pain, most fearful headaches, and frightful spasms; and should you suggest any portion of her body, from her head to her heels, as possibly exempt from pain, she often resents the insinuation, and declares *that* is the very part where she suffers most. Whilst she tells you all this in a sort of whine, her features don't show indications of any agony, and, if you watch her, you will find she over-acts her part. Utterly indifferent to the anxiety of parents and friends, or to the trouble and expense she causes, she seemingly finds gratification in watching the unwearied efforts of those around her in doing their best to comfort and help her. Whilst putting on an air of the most abject listlessness whilst you look at or speak to her, if you talk at her you will learn that she has both eyes and ears; if you assist her in anyway she makes herself as helpless as she can—a dead weight. These creatures not only deceive everyone around them, but in time they succeed in deceiving themselves. Were it not so, I cannot understand how they continue playing such a sorry game for so long, and with so much strain and fixity of attention to the exclusion of everything else as I have seen them do. If we push our enquiries a little further, we generally discover that there is some obliquity of the moral sense; an ungratified whim or disappointed affection at the bottom, and that whilst the patient will be abed for weeks, or on a couch, quite unable to to anything, suddenly some evening she will announce her intention of going to a ball, where she will dance the whole evening; or she may take it into her head and mount her horse, and, should she meet with hounds, join in the chase, and, what is more, ride straight.

Before giving illustrative cases of each, just one word on what has been called Alcoholic Neurasthenia. I have read of such, but never seen one. I have met with excessive drinking in both classes of the broken down, but the nerve failure preceded the indulgence, and was clearly its cause. I dare say I have seen as much drinking among men and women of all classes and ranks as most, but I do not hesitate to affirm that, during the whole course of my experience, I have never known intoxicants, even when taken in great excess, produce the slightest approach to the form of debility we find here. I have seen locomotor ataxy and acute multiple neuritis follow in the wake of the drunkard, but never neurasthenia. I am not going to defend intemperance in alcoholics, although I agree with Sir Wm. Roberts in looking on them as powerful for good, as they are, under certain circumstances, productive of evil; yet when I find it associated with nerve exhaustion I shall always look on it as the natural outcome of the knowledge which is universal, that a stimulant will give a lift to one when down that nothing else can, and that generally in the first instance the *glass* has been brought to the patient's lips by her urgent needs, the pressure of friends or advice of one of ourselves.

Hitherto I have spoken as if neurasthenia were to be found among women only, but such is by no means the fact, as it is quite as common, if not more so, among men. Only the symptoms with them differ in many essentials, and are much more of a negative character than positive. Five and twenty years ago, before the term neurasthenia was introduced, I described this form of nerve exhaustion in an article I then published under the title of "Jaded Brains," and as I have not met with a more graphic description from another pen, and could not write a better now if I tried, I shall quote two or three sentences from it.

"Used up, undone, jaded, are no uncommon expressions; nor are they alone descriptive of the old and infirm, of the votaries of pleasure, the victims of dissipation—or even of those whose bodily powers have been enfeebled by disease, or underminded by want and privation. They are more frequently made use of to express a state of mental or nervous exhaustion than bodily, and have a totally different signification to the terms tired, fatigued, weak, which are applied to the condition of body consequent on unusual exertion. Is there a medical practitioner of the present day, of even moderate experience, who cannot testify to the fact that these, or similar expressions, are being constantly made use of by many patients in the prime of life, and apparently in good health; at least, whose outsides bear no visible sign of decay within! How many among the active, bustling, money-hunting men of the world—because they are going too fast, working at high pressure; because their business is no longer the plain, matter-of-fact concern it used to be, but is accompanied with a vast amount of excitement, and demands an expenditure of nervous energy which they cannot afford—complain of being used up. How many tell us that they are fit for nothing, that their minds have become unhinged, or have lost, in a certain measure, the power of continued thought; that the writing of the simplest business letter, which ought to cost them no trouble, is a task which can be accomplished but with greatest difficulty; that they have ceased to take an interest in everything—wife and children are indifferent to them; everything alike and everybody is a bore; with spirits broken and fast-failing strength, they apply first to one thing, then to another—wine, brandy, tonics, each has its turn; by these the jaded brain is urged to make another effort in the race for wealth, position, or power, just as the pumped out racer is urged with whip and spur to keep the lead, and too often, with like result—a breakdown.

"During the last quarter of a century, science and art have gone hand-in-hand in furthering our progress towards a more perfect state of civilisation than has at any previous time characterised the history of man. By their means

labour, muscular, or manual labour—is being rapidly reduced to a minimum, and mental or brainwork is being proportionately increased.

"Is there a handicraft whose labour has not been lightened, if not removed, by recent inventions? I leave our mills and manufactories, hydraulic powers, steam hammers and steam ploughs, machinery of every kind and for every purpose, to proclaim the fact—that the muscles and sinews of man are no longer required to accomplish the kind of work they were but recently obliged to perform.

"This being the fact, it is not among the working classes that we meet with examples of nerve exhaustion; the increase of machinery I have above alluded to, and its very general application, has not only assisted most materially in lessening the burden of toil to them, but it has raised their general intelligence; its effects upon the great mass of the people have been for good. It is otherwise, however, with many an inventor of that very machinery which has modified and improved the condition of the artisan. How much brain has he spent, and with what results to himself, upon accomplishing what looks so simple when done? It would furnish a most instructive and melancholy history if, with mechanical improvements and scientific discoveries, we could obtain an insight into the condition of their authors. How many have broken down before their plans were matured, after months, aye, years, of anxious experiment and doubtful strife? How many, even when their endeavours have been crowned with success, find themselves bankrupt in health, and totally unequal to enjoy their well-earned riches and reputation?"

Moreover, "it is no rare thing to find the pioneers of science and art pretty hard up as regards cash, and too willing to pinch themselves and their families concerning even the very necessaries of life, in order that every possible shilling may go to the development of the one grand idea, which is, at the same time, the offspring of their thoughts and the master of their actions."

TRUE NEURASTHENIA.

Case 1.—Young lady, in affluent circumstances, of good family history, and in perfect health, chose to nurse a favourite brother in a long illness, the result of over-exertion in athletic sports. For eighteen months she seldom left the sick-room, and during the whole of this time never felt the slightest over-fatigue. The brother died. For a time, although sleepless, the girl seemed equal to anything. At the end of a month she felt a weary aching in her spine, which strong pressure relieved. This was shortly followed by a feeling as if, in walking, her feet were far too heavy, and they had to be dragged along. Then migraine put in an appearance. She noticed that she could not even force herself to take an interest in anything. Her favourite studies, pet animals, and friends became not only indifferent to her, but a source of annoyance. Suddenly her strength failed, and she could scarcely walk a yard, or stand without help. Pain in her head increased, and when it was absent she felt as if there was a weight on the top, and as if the inside was stuffed with cotton wool. Palpitation, with intermittent cardiac action came next, and left a sense of choking, as if some one grasped her throat. She could take plenty of nourishment, but it never did her any good, and she had a feeling of sinking at epigastrium. She fought against her troubles; managed even to dress herself with sittings down and patience. She, however, could do nothing except, as she said, eat and sleep. Motion of any kind caused great exhaustion, and exercise in a carriage, whether on road or rail, made her suffer agony as if a gimlet was at work in her spine. This was accompanied by sea-sickness, as she called it. The erect posture, if maintained for more than a quarter of an hour, did the same thing. She looked exceedingly well in the face, and the body was fairly nourished; functions normal. She always tried to appear as bright and cheery as possible; was so pleased when she could tell me she had been able to sit up a little longer, or walk but a step or two further. She always felt the air of Harrogate to give her life and spirit.—Three summers, under my observation, ultimately regaining perfect health.

Case 2.—Young lady, in good position, and as far as I can make out—although weak as a child without any neurotic proclivities—she had been neurasthenic for five years before I saw her, and at my request she has furnished me with her history previous to my visiting her. She begins by saying you have always seen my best side; I am only a poor creature, with all sorts of horrid feelings to fight against, and often failing in my efforts. I shall only give an extract of her account. When at school, in town, suffered from a constant feeling of tiredness in back, as if it never could be rested; she fought against this, fearing she might be looked on as shamming. On returning home she had a great deal of trouble, now even painful to look back upon, but this had nothing to do with the *affections*. Six months after she broke down, and her medical man could not say what was specifically at fault. For two years she suffered from low spirits, yet she went about like other people, telling no one of her ailings—attended to her duties—and, whilst feeling wretched, she could point to nothing definitely wrong with her, and looked in good condition. She actually persuaded herself that her feelings were all nonsense, and her great aim was to have plenty to do, and so forget them. Suddenly she collapsed; she went to bed as usual, awoke in the night with a dreadful attack of giddiness and sickness. All next day this continued, and if she moved it felt as if some one was stirring up her head with a stick, or as if two waves met in the middle, and had a struggle for a few seconds. For days she was so ill she was allowed to lie in bed, without its being made. The slightest sound caused agony. For three months she remained in much the same state, with the addition of spinal neuralgia. When able to travel she went to the North of Scotland, where strength seemed to pour into her, and in some weeks she returned home, able to walk a little. For a year she did nothing; then she overdid herself district visiting, and attending to many things in her brother's parish, which had been sadly neglected by the former vicar. She went on struggling for a time, requiring to exert all power of self-control to prevent people knowing she was so utterly unequal to the work she had taken in hand—and so irritable and wretched, that sometimes she could hardly bear to be looked at or spoken to. This went on till the work and excitement of a bazaar finished her. A frightful attack of shivering was followed by utter prostration. Recovering partially, she then went in for assisting at Christmas Church decorations, and that was more than enough: she felt as if she were paralysed, when sitting her legs trembled, and if she moved her foot the least, a horrid creeping sensation went all up her. Since then, for the past three years, she has been almost entirely confined to her back, suffered from nerve-storms, affecting head and spine, from gastric neuralgia, palpitation, irritability of special

senses, and nearly total loss of all voluntary muscular power, the slightest attempt knocking her to pieces, and causing her to wish the floor would be so kind as to open and hide her. The agony felt is sometimes very great, and yet she would rather suffer anything than let her friends know that her self-consciousness was so terrible. She adds, I can tell you anything because you have never laughed at me, nor been surprised at my apparently foolish feelings, and comforted me by saying I had nothing to be ashamed of or reproach myself with. She adds, I feel better now than I have ever done. I get out every day with my chair close to the sea, the smell of which is more delicious and refreshing than the scent of any flowers, and makes me feel as if I were growing stronger every minute. I have much less pain in my back, and altogether wonderfully well for me. Her description of her symptoms is so good, so faithful, I sha'nt spoil it by adding more, except that she is one of the most gentle and unselfish creatures, and that her sufferings have been lightened in a great measure by her faith in a religion void of cant.

FALSE NEURASTHENIA.

Case 1.—Young lady, æt. twenty-eight, suffered for seven years from the most marked form of neurasthenia. Her debility was so great she lay on the bed or a couch, complained of neuralgia in every portion of her body. Sickness, anorexia, palpitation, insomnia, intolerence of light and sound, was much given to hysterical fits of both crying and laughing. Had been under many doctors, tried many systems and changes, all to no purpose. At last some enemy of mine suggested Harrogate waters, and I was required to meet the patient and superintend her removal from an invalid carriage at my end, as her doctor had seen to her being carefully laid out in the same when starting on her journey. On receiving her in my arms I was struck by a searching look she gave, and also by the marked effort she made to appear as utterly helpless as possible. She could not put an arm round my neck; it had to be placed for her. On my way with my dead weight, I intentionally stumbled, and at once she clutched me, and then I said to myself you are an utter humbug, and I'll find you out. On my second visit I said to her, "You really are so weak I must have a first-class nurse to wait on you." This she strongly objected to, but I insisted on it. I told the nurse that she was to report faithfully to me, all the symptoms presented day by day. For a fortnight my patient remained exactly in the state I found her; pains, palpitation, sickness, diarrhœa, constipation, faintness, swoons, all had their turn, and yet there was something about the woman that told me I was right in my suspicions. At last I obtained proof positive. I had always driven to her lodgings at a certain hour. She could see me, from her couch, stop at her door. I knew the nurse went out every afternoon from two till three, so, having paid my usual visit in the morning, I walked past her window when she was alone. I looked in; I saw her sitting up on the couch, doing something with her hands. When she caught sight of me she threw herself most vigorously down, pushed whatever she was working with under the covering, and on my going in I found her greatly flushed, looking as if she would have liked to have scratched my eyes out, but as helpless as ever. I asked for an interview with her father, told him what I had seen, that I felt as certain as I was of anything that his daughter was not the invalid she made herself out, and that I could do nothing for her, and declined further attendance. I was heartily abused. The girl kept up her old game successfully for, I think, a couple of years, when suddenly she appeared one day moving about like any other being, and assumed her proper place in the father's household.

Case 2.—I was consulted in the case of a married lady, who for years had been the subject of neurasthenia. She was moved about in an invalid carriage, or a reclining board on wheels. She was very helpless, her nurse and maid had to wash and dress her like an infant; but I noticed the effect was artistic, one or other held a gaudy parasol over her head when out for an airing. Ribbons of various colours, and fine lace helped to set off a pair of wicked black eyes. There was a fetching air about her that struck me the first time I saw her. Her physician told me he suspected some uterine mischief, and he had called me in in order that I might ascertain the condition of that organ. I at once proceeded to examine, but as quickly desisted, left the room, and told the doctor that his patient was a nymphomaniac, and the less we meddled with her womb the better. For years she played the invalid, lying in bed for months. She again came under my care; this time she took me into her confidence, and although she was the greatest humbug I ever met, I could not help feeling pity for her. She would tell her husband she had not broken her fast when he came home at 7 p.m., when I knew she had eaten three full meals, with "stout" at two of them. That she could not retain her water, when no one ever found a wet thing about her. At last he took her to London. She was put into a home, had her clitoris removed, was kept isolated for months, and returned home exactly as she left it. She was constantly seeing some fresh doctor, whose attention was invariably directed by the patient to her uterus, urethra, or bladder, the result being the introduction of speculum, dilator, or catheter, and this went on till menstruation or something else ceased, and then she became a strong, active, and useful member of society.

I have but a few words to say on the management of true neurasthenia. First of all, if we are to be of any use we must gain our patient's entire confidence, and this can only be accomplished by showing her, and making her feel, that we take an interest in and sympathise with her. 'Tis no use treating these cases as we do the ordinary run of patients—feeling the pulse, looking at the tongue, using stethoscope, sphygmograph, or any other graph. We must sit down and interest our client. Don't ask her about her symptoms; tell her how she feels. Let her see you know something of the pranks nerves can play. Throw into your manner and conversation as much sunshine as you can. Give her something pleasant to think about, and make her look to your visit as the most agreeable portion of her day. If you can get her to take an interest in one of your patients, whose condition is worse, and whose wants are greater than her own, you will decidedly have made a good move. Let there be no hurry. By and by, when you and she have got on good terms with each other, explain to her the nature of her illness. Make her understand that she must be guided by you in everything; that for the present she must bow to the inevitable, and submit to the strictest rules as regards her *self*-management. Above all, make it clear she must live within, not up to her powers. If she can walk for ten minutes let her stop at eight; if she can read or write for so long without discomfort she must give both up in time to prevent that feeling. Put also a bridle on her tongue, and visitors and friends must be made to cut their conversations

short, and arrange that she may not have too many one day and none the next. Everything must be done regularly and in order. A system of diet adopted and enforced best suited not only to her requirements, but her capacity as regards digestion and assimilation defects in these functions must be remedied by suitable treatment. The entire surface of both should be washed with soap and warm water each morning, and dried carefully with warm towels.

At night, general friction with warm olive or cod-liver oil should be employed, as not only a means of promoting circulation and tissue change, but as being conducive to repose; in this case a flannel nightgown is essential. Passive exercise in open air, and exposure to the sun's rays, should be made compulsory, in Bath chair or carriage; if these are not to be had, rig up a tressle, carry her if she can't walk to it, and let her lie there for so many hours each day. See that her bedroom has a plentiful supply of fresh air, and whenever safe let her sleep with a piece of her window open. As to stimulants, when these are necessary, I prefer stout and unsweetened or sparkling coca wine to anything, and these should always be taken with food. In the matter of drugs I have little to say; I have tried every tonic, with most unsatisfactory results. Aperients are often required, and I prefer rhubarb, aloes, and sulphur to salines. Sedatives are of course absolutely necessary, and the bromides are by far the safest and most effectual. Opiates and chloral should be held in reserve and given with judgment. Massage, electricity, and hydropathic appliances I have found most disappointing, but change of scene and climate highly beneficial. Whilst advocating these, I must ask you to remember that travelling is badly borne, and on advising a visit to any health resort, time must be allowed in order that the fatigue of the journey there and back may be more than recompensed by the visit. The most perfect restorative I have yet met with is a long sea voyage in a well found high-class steamer, and when that can be put into practice it will be found the cheapest and surest means of cure. Isolation in a home I consider a most questionable step, and altogether uncalled for in cases of true neurasthenia, however suitable to what I have described as false, then I think it likely to prove highly beneficial. At the same time I should prefer that it be carried out in some public institution, under the charge of a medical staff, and at a reasonable expense. I do not hesitate to say that in my opinion all private houses, set apart for the reception of special patients, should, like lunatic asylums, be under some form of Government inspection. I would not venture on making such a suggestion unless I had good grounds for so doing, from a knowledge of what takes place occasionally in these establishments, as well as what I have seen happen to certain patients after their discharge from isolation and return to society.

At the beginning, I said that the remarkable increase of neurotic patients during the last forty years, constituted one of the most striking features of our time. But don't let us forget that nerves existed and were recognised in the dark ages; their symptoms may have been misinterpreted; their treatment by charms, incantations, and compacts with the devil, in whose personality and power people then, as now, believed, a little too speculative, still I have no doubt much good resulted from the powerful direct appeals made to the imagination of the patients. It is recorded that about the time of the union a blacksmith practised in the parish of Kilmartin, in Argyllshire, who had a specific which cured all sorts of fits and nerves. This son of Vulcan was a man of singular power and presence; his command over the muscles of his brawny arms was marvellous. When a case was brought to his smithy, he placed the patient's head on the anvil, face upwards; he then took his big hammer in both hands, and, swinging it high in the air, he made his approach with ferocious aspect, as if he meant to kill at one blow. Down came the hammer, only to be arrested when unpleasantly close to the poor thing's nose. The effect was miraculous; the shattered nerves were restored, the fits cured, never again to require even the application of a burnt feather!

ON OSTEITIS DEFORMANS, OR SENILE PSEUDO-RACHITISM.[1]

By S. Pozzi, M.D.,
surgeon to the lourcine.

Our knowledge of the disease to which I wish to direct the attention of the Congress is of recent date. On November 14th, 1876, Sir James Paget read his first paper on the subject before the Royal Medical and Chirurgical Society of London. The title of this work was as follows: "On a Form of Chronic Inflammation of Bone (*Osteitis deformans*)." It was published in the sixtieth volume of the Medico-Chirurgical *Transactions* (1887; p. 37).

In chronological order, then, come the observations published by Charters, G. Symonds (in Guy's Hospital *Reports*, 1880-81); an additional paper by Sir James Paget (in the Medico-Chirurgical Transactions, 1882); several observations made before the Pathological Society of London by S. Willis, Charters, G. Symonds, Treves, Henry Morris, Barlow, Bowlby, Turner, etc. A paper, which I have not been able to consult, has been published in America by Ellinwood, in the *Western Lancet*, San Francisco, 1883. In France I have not found any other document on this curious affection than the very short notice which Dr. Vincent has consecrated to it in the French translation of the "International Encyclopædia of Surgery," IV., p. 359, he was content with giving a *resumé* of the papers of Paget, without adding any new cases. This has induced me to report *in extenso* the following cases, one under my own care, the other two graciously communicated to me by Professor Ollier. I will then give a sketch of the malady as it is made known to us in different works up to date.

Case 1 (reported by M. Thouvenet, Interne).—*Osteititis Deformans—Incurvation of the Tibiæ and of the Bones of the Upper Extremities—Fungoid Osteitis of the Finger—Otorrhœa (Senile Scrofula)*. Louvel, cap maker, aged sixty years, patient at the Hospital Pascal. *Antecedents:* health good; no signs of scrofula in infancy, neither syphilis nor rheumatism. Commenced to menstruate at seventeen years. Regular up to forty-five years, epoch of the menopause. Mother died at forty-five years in consequence of a disease which she could not specify. Father not known. Three sisters died after long illnesses. Earning very little, she was for a long time badly nourished, living for a long time on a diet chiefly composed of vegetables. The osseous affection, with which she was attacked, commenced at the age of fifteen years. The left leg first became the seat of acute pain, localised in the heel and knee. This pain, which persisted during four or five years, only appeared when the patient was more

[1] A paper heard at a French Congress on Surgery.

fatigued than usual. In process of time the tibia became equally painful. Her work was never interrupted; at the same time she suffered in the left leg she remarked that it was deformed, the tibia formed an anterior curve and progressively reached the degree of deformity I am about to describe. It was only a year since she noticed that the right leg was also deformed (fig. 1).

Actual State: The left leg describes a curve on the anterior convexity. The tibia is considerably thickened. The epiphysis, especially the superior, are especially increased in size. The peroneus is neither augumented in size, nor changed in the direction which makes the interosseous space very great, especially in the middle part. The leg is flattened from outside to inside. The muscles of the posterior region

Figure 1.—Front View.

Figure 2.—Profile.

are held like a cord round the shortened tibia, which forms the arch. The right leg is less deformed, the tibia shows a shortening at the interior convexity. The patient lying on her back, the two heels together, the internal tuberosities of the tibiæ were at a distance of twenty-four centimètres The left leg was slightly shorter than the right. In walking, the patient limps and rests on the external part of the left foot. Her height has considerably diminished. She walks short. This seems to me to indicate an alteration in the vertebræ.

The iliac bones and the thorax do not present any deformity. The skull does not show anything notable. The left indicator was attacked some nine months since. It is swollen, fusiform, red, and shows several little orifices from which run pus—upon pressure there is slight crepitation. The left humerus exhibits a shortening, both anteriorly and internally less pronounced; it is increased in size. The patient is left-handed. The right radius in the lower part is curved backwards. Movements of supination are performed with difficulty and incompletely on this side. There was a running from the ears, which had been going on for about a month, of a sero-purulent liquid, which has now ceased. Hearing is rather bad. Appetite good; indigestion good. Urine normal. Nothing wrong with the lungs or heart. The patient was placed on an alimentary diet, with cod-liver oil.

The bad finger, which was so painful, and the seat of constant suppuration, was taken off on the 15th April. M. Pozzi performed metacarpo-pharyngeal disarticulation and resection of the head of the metacarpus; the latter being softened and breaking down under the bone forceps. In the sheath of the flexor of this finger, in the palm of the hand fungosities existed, which determined, at two points, small abscesses, which opened spontaneously. The invasion of the sheath took place progressively. This had been established when the patient was under treatment. A longitudinal incision was made at the top of the diseased sheath, which was scraped and cauterised with the thermo-cautery, Phenic dressing. Rapid cure after operation. Histological examination revealed the tuberculous nature of the osteitis.

Case 2 (communicated by Professor Ollier under the

following title) :—*Local Osteomalacia of the Tibia having a debut of nineteen years—Increase of Bone—Deformity of Condyles—Curvature of the Diaphysis—Gouty Diathesis* —M. F., aged at present seventy years, consulted me in 1865 for a painful swelling of the diaphysis of the left tibia without any deformity. For three years vague pains, uneasiness in the leg, some varices. No previous acute rheumatism ; some digital nodosities, but not marked. No rachitism in infancy, no syphilis. Three or four years before the affection of the tibia, swelling of the knee on the same side, which yielded to the application of blisters. The articulation yet remains a little more stiff. Some crepitation. I ordered the patient iodide of potassium, Vichy water, rest ; flying blisters if the pain persisted. I did not see the patient again for seven years—March 23rd, 1872. She told me that on August 15th, 1871, she had a fall on the pavement, which obliged her to pass three weeks in bed. In this fall she had heard a crack, without being able to say whether it was in the tibia or on the knee. At any rate, as the result of this accident, the projection of the tibia became apparent. Before this time Madame F—— had many falls, which increased the painful sensations in the leg ; but what I wish to note is, that the projection on the tibia did not form immediately after the fall on August 15th, 1871, the patient only perceiving it four or five months afterwards. The curvature is not abrupt ; there is no angular projecture as in fracture. The bone diminished in consistence, but yielded gradually under the weight of the body.

Special Articles.

MEDICO-MECHANICAL GYMNASTICS.

In a very interesting book published by Chapman and Hall, in 1864, entitled "The Muscles and their Story from the Earliest Times," by Dr. John F. Blundell, we have a very instructive account of the various processes adopted by the ancients for the purpose of strengthening the body and curing its ailments. The whole art of education in ancient times was in fact embodied in the well-known maxim, *mens sana in corpore sano.* A mutual balancing of the two forces, physical and mental, was aimed at.

Dr. Blundell traces the development of medical gymnastics from the time of Hippocrates, showing how the Greek and Roman youths were trained not only for war but for peace, and how the citizens armed themselves by games and exercises which better fitted them for daily toil.

The medical aspects of the system of training are very important, and "In Rome during the time of Marcus Aurelius the designs and qualities of exercises were under public inspection, and the pupil-teachers were ordered to be selected from the gymnasiums, owing to their superior knowledge and experience of what were judged, by the different authorities on exercise, to promote health and a good habit of body" (p. 38).

The great art consists in finding out what exercises suit ; what are best for certain individuals, so as to strengthen the natural habit of the body. Dr. Blundell's book is well worth reading, more especially as we are returning somewhat to the practices of the ancients in re-introducing massage and medical gymnastics.

Massage is now a fashionable as well as useful form of medical treatment. It has passed through many phases, and

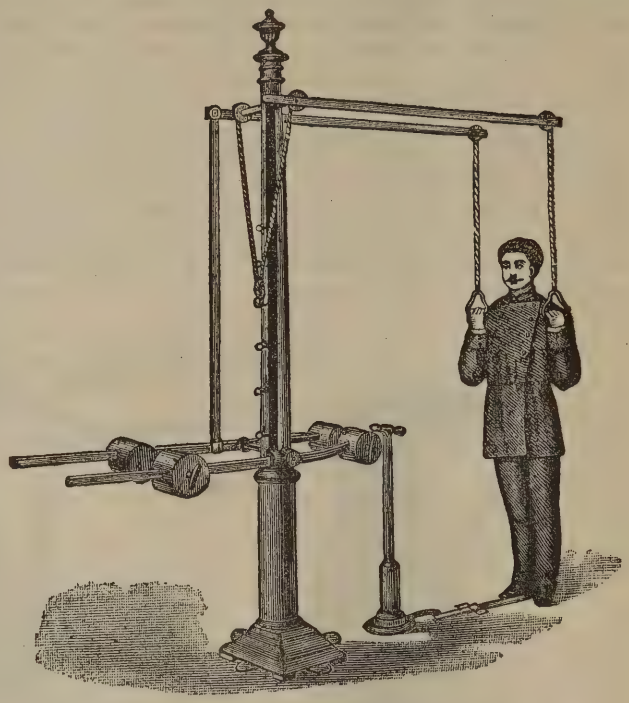

Fig. 1.—Arm Depression and Flexion. (An illustration of "Active Arm Movements.")

we have its latest development, in the introduction of special machinery for the purpose. Since Dr. Zander, in 1865, opened at Stockholm, an institution for medical gymnastics,

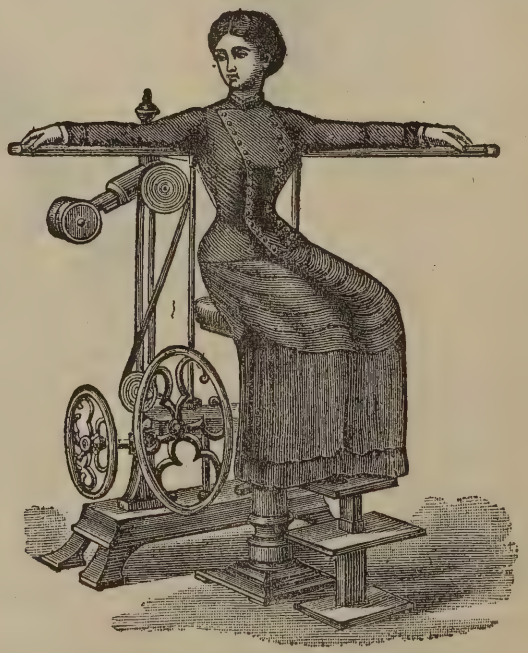

Fig. 11.—Drawing the Arms together (Adduction.)

the method of treatment has widely spread, and his apparatus are to be found in many of the foreign health resorts,

Hamburg, Baden-Baden, and in many of the principal cities as St. Petersburg, Paris, etc.

Dr. Zander's apparatus is meant to take the place of the *Masseur or masseuse*, as he has proved by practical experience that by machinery he can better adapt the exercises to the patients' requirements, and besides that, with a number of automatically acting machines, a larger number of patients can be treated at one time. We are able to present our readers with a description of some of the machines in use at the Institute of Medical Gymnastics at Baden-Baden, taken from two papers, one by Dr. Brown in the *Satellite*, Philadelphia, and the other Dr. Mazzuchelli in the *Journal of Surgery and Antiseptics*.

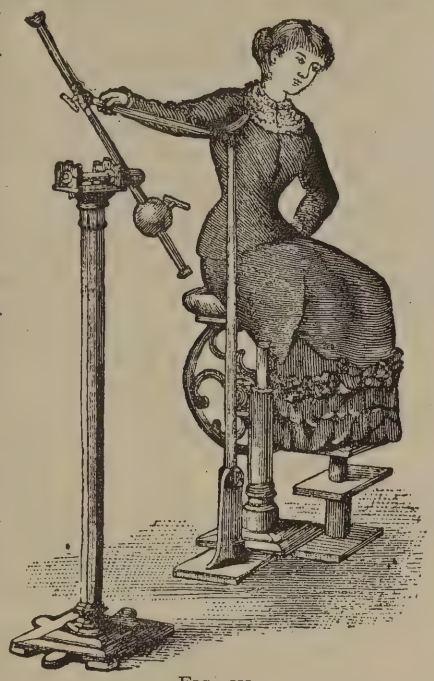

Fig. III.

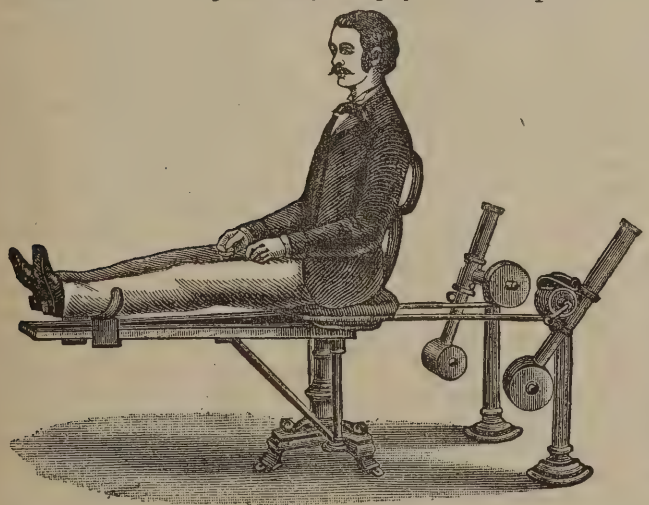

Fig. IV.—Leg Spreading (Abduction). "Active Leg Movements."

Dr. Zander's apparatus are divided into two classes.

a. Apparatus moved by the patient's muscular efforts.

b. Apparatus moved by steam or gas engine.

a. These apparatus are divided into groups.

1. Active movement of the upper limbs.
2. Active movement of the lower limbs.
3. Active movements of trunk.
4. Movements of equilibrium.

b. Apparatus for passive movements.

c. Apparatus for mechanical action.

1. Movements for shaking.
2. Movements for *tapottement.*
3. Movements for *petrissage.*
4. Movements of massage *a friction and frottement.*

If we look at some of the drawings, we shall see how the exercises are carried out. Fig. 1 represents the apparatus for the lowering of the arms, with reflexion at the cubital articulation. The patient, holding the upper limbs aloft, takes the handles and lowers the arms so that the hands come in front of the shoulders, the elbows touching the thorax, as shown in the illustration. By this motion the patient lifts the weights placed at the inferior part of the machine. The position of these levers varies the resistance, and therefore the amount of muscular force needed to overcome it. With this movement slowly done a number of times, the strong muscles of the back and chest are exercised, as they are compelled to draw down the humerus, which has been extended aloft. In this exercise the flexion of the elbows is nearly altogether passive; thus the flexors of this articulation do not act much. This exercise is intended to develop the thoracic frame. Adduction of the arms is brought about with the apparatus, fig 2. The patient, in a sitting posture, holds his arms extended laterally in a horizontal position, so that the arms rest comfortably at the level of the apparatus, while the hands grasp its extremity lightly. The arms are then carried forward until they meet, thus overcoming a resistance opposed by weights placed behind, a resistance which, as in every other form of apparatus may be varied with the position of the weights. This movement exercises

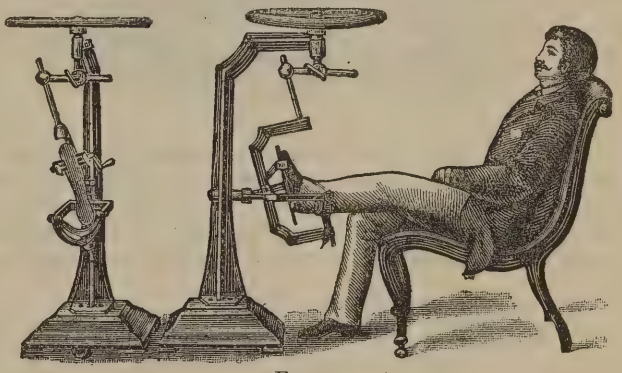

Fig. V.

the muscles of the anterior portions of the thorax and of the humeroscapular articulation. This exercise also serves to develop the thoracic frame. Circumduction of the arms is secured by apparatus, fig. 3. Active moments of the lower limbs are brought about by such an apparatus as fig. 4. This is for abduction of the legs. The patient seated, places the legs over two boards, the ends resting on crutches. The different positions given to the balls serves to establish with accuracy the amount of muscular effort required.

In fig. 5 we have an apparatus to circumduct the foot. The patient sitting and extending the limb, places the foot against the opposite movable pedal: then with a movement of circumduction of the foot, a fly wheel placed above, is notched, a small graduated rod connected with the hub of the wheel serves to establish the length of the arc of circle described by the foot during the exercise. This exercises both the flexors and extensors of the foot and, moreover, the rotation gives elasticity to the articular capsules and the ligaments of the foot.

In fig. 6 we have an example of the class of machine performing mechanical massage, the arm passing through the wheel is gently rubbed, and thus friction is maintained. Other parts of the body can be similarly rubbed by appropriate instruments. The expense of these machines varies from 500 to 1,500 marks a piece; they run with steam or gas

power, and make very little noise. They are only used under medical direction, and the assistants who carry out the treatment are assisted by printed directions. The instruments are only used for a few minutes. In the practice of massage,

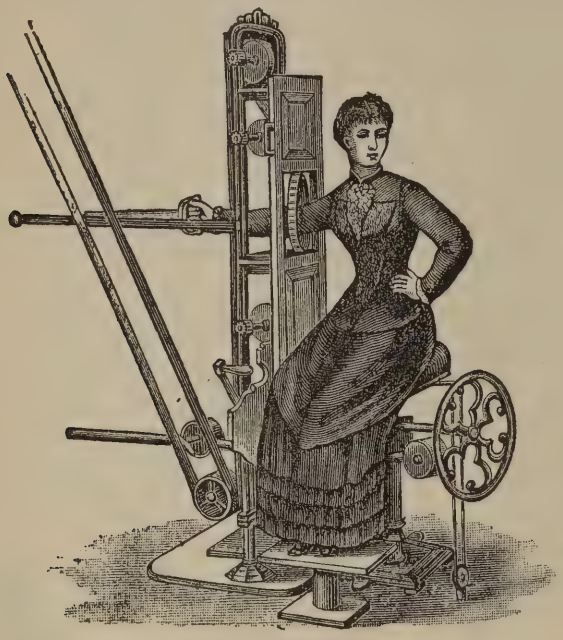

Fig. vi.

one great mistake is made by many; too much is done at one time, an hour is frequently spent by the rubber on one patient. This is over-doing it; a quarter-of-an-hour or twenty minutes is ample for one sitting. At the establishment at Baden-Baden the arrangements are almost complete.

HEALTH RESORTS OF THE WORLD.

XXVI.—GREAT MALVERN.

By an old Oxonion.

In August, 1857, I was only a tiny boy, and then for the first time, I was, much to my delight, taken to Worcester. The Midland in those days was well managed and as popular as any other leading line, but as no railway extended to Malvern, we had to alight at Shrub Hill, and continue our journey by coach. The evening was lovely, and as I was perched on the top of the coach to see the country to the best advantage, I can still remember the pleasure I felt going along Bridge Street and across the Severn Bridge, and past Powick, with its stately trees and gentle ascent, to Malvern Link and Great Malvern. The verdant fields, the large orchards, the majestic hills in front, looking to my childish fancy like a second Himalayan range, made a *tout ensemble* unlike anything that I had, up to that time, ever seen. Malvern was even at that remote time a favourite place, and Birmingham and the Black Country, and still more distant places, sent during the summer months small contingents of visitors and invalids, but it was not until the opening of the railway, shortly after my first visit, that the place became easily accessible and popular. Long before I was born the town had become famous for its vast hydropathic establishments, and wealthy sufferers had, in considerable numbers, when the difficulties of the journey were remembered, gone thither and passed through its severe regimen and total change of life. The hydropathic establishments of those days still flourish, though the great medical names of thirty years ago are nearly forgotten. Dr. James Manby Gully I frequently remember seeing riding about, and his singular resemblance to the great Napoleon was pointed out to me. Of course I did not understand what was meant by it, and it was not until the winter of 1875-76, when I saw him again, as a friend, in London, that I noticed that extraordinary likeness. In 1857, Dr. Gully was the great light of Malvern; his reputation, destined to undergo total eclipse, attracted innumerable rich clients, and he made the town famous while the town regarded him as its greatest benefactor, and most illustrious citizen. Dr. Ralph Grindrod was also in the zenith of his fame, and, though somewhat advanced in years, was still vigorous and active, and was naturally proud of being the author of the once famous "Bacchus," a work which, though now superseded and nearly forgotten, was, in its day, a kind of revelation, and did the temperance cause incalculable service. Since then both Gully and Grindrod have passed away, and the latter is represented, though in a different house—Wyche Side, Malvern Wells—by his son, Charles. The former has left no representative of his name in the medical profession, and his lamentable and unpardonable downfall shook the faith in human nature of many excellent people.

Malvern is built along a fine, broad road skirting the hills, and extends some miles along that road, from the Link, through Great Malvern, to Malvern Wells. The principal part of Great Malvern stands at the foot of that noble hill—the Worcestershire Beacon, and is considerably raised above the fertile Severn Valley. It is excellently built, covers (considering its small population—some 7,000 or so) a large area, includes some handsome detached and semi-detached villas, has a popular public school, a beautiful Priory church, several handsome hotels, capacious enough to accommodate hundreds of visitors who have money enough to pay for the comforts of an English first-class *pension*, and a good display of large and handsome shops. Altogether, the town is picturesque, clean, and attractive, and is far pleasanter than many other old watering places.

Standing just in front of the Foley Arms, close to Lamb's Library, one is in the midst of a beautiful and busy town, and yet not ten minutes from the open country. Up any turn towards the hill, and in an quarter of hour the town is lost to view, and the country is around us. Malvern has capital well made roads, which ascend by easy zigzags, and richly wooded heights, commanding an endless variety of views over the plain; every turn presents the valley in a fresh light, so that few excursions can be more fascinating or make a deeper impression.

Lodgings abound, and so do furnished houses, and though the season is not long, from July to the end of September, and the lodging-house keepers have to make the most of their opportunities, I do not think that prices are on the whole exorbitant; at any rate, in winter and spring accommodation is cheap and the choice bewildering. June would be an excellent month for a visit to Malvern. It is unfortunate that the modern division of the School year into three terms, and the consequent lateness of the summer holidays, keeps many people from seeing Malvern and other charming pleasure resorts till the longest days are past and the autumn tints are beginning.

St. Ann's Well is one of the principal features of the

little town. It is a quaint house, some 400 feet above the Library, on the side of the hill, looking toward Worcester, and about fifteen minutes' walk from the middle of Great Malvern. Not far from the Well, famous for its cool and delicious water, and towards the west, is a mass of rock, from the summit of which a noble panorama over the extensive plain presents itself to the eye. I once stayed at Hill Cottage, close to this rock and not far from St. Ann's Well, and I passed more hours than I could well count sitting on that rock, looking over the plain, the town, the church, and the shops spread out at my feet. Malvern is credited with an exceptionally mild climate, and is said to be a fortnight earlier than Hereford, while residents say that frost often occurs above and below the town, although the town itself is unaffected; a meteorologist would not perhaps find it difficult to give a plausible explanation.

Among the objects of special interest are, of course, the hills—especially the Sugar Loaf and the Herefordshire Beacon—the Wyche, a strange, deep cutting through the hills, and the imposing remains of a British camp half way on the road to Ledbury and not far from Eastnor Castle. Tewkesbury, with its majestic Norman Abbey, recently splendidly restored, is only a few miles off, and is reached in half an hour by rail from Great Malvern, while Worcester with its noble cathedral and the tapering spire of St. Andrew's Church on the one hand, and Ledbury on the other, with its rich foliage, luxuriant orchards, grand old church, with its superb west porch, detached lofty bell-tower, and quaint rural simplicity, are both easy of access by rail, and full of interest. Hereford, too, is not far off, while Brecon furnishes material for more than one day's excursion.

Malvern is well laid out, and happily combines the charms of country life with many of the advantages of a town, and is not without great attractions in the shape of good lodgings. It is just the place for a large family anxious to fly from the endless streets and noisy crowds of large towns, and it deserves even greater popularity than it seems to have in these days of keen competition. Malvern, for people needing special water cure treatment, is equal to Matlock or Buxton.

Very large crowds of excursionists reach the town on Saturdays and Mondays from Birmingham and Wolverhampton, but many of them idle the day away on the common near the Link, or in the principal street, and they certainly interfere very little with the wealthier visitors, who can easily keep out of their way. In short, Malvern has exceptional advantages of position and no drawbacks, except that its steep roads make walking difficult to the aged and the inactive.

XXVII.—THE SOUTH WALES BORDERS AND THE GOLDEN VALLEY OF HEREFORDSHIRE.

By Alfred J. H. Crespi, of Wimborne.

Sometimes standing on the summit, or, still better, halfway up the western face of the Worcestershire Beacon, you see, stretching at your feet, like another Garden of Eden, a vast plain, with here and there low ridges of hills. On one of the few clear, bright days of an English summer, when the air is transparent, the verdure richly bright, and the sun shining with that subdued brilliancy so much more grateful to the eye than the dazzling fervour of hotter climes, no scene can well be conceived more typically English. However dry the season may have been in Dorset and Hants, the grass is always green and the leaves always fresh on the borders of Monmouthshire and Breconshire. "In some quarters," says Canon Kingsley, "especially in the north-west of England, the soil is poor, because it is marked by that boulder clay of which I have spoken in other places, but the rich red marls, wherever they come to the surface, are one of God's most precious gifts to this favoured land. On them one finds one's-self in a garden, amid the noblest of timber, wheat, roots, grass which is green through the driest summer; and, in the western counties, cider orchards laden with red and golden fruit. I know, throughout northern Europe, no such charming scenery for quiet beauty and solid wealth as that of the new red marls; and if I wished to show a foreigner what England was, I should take him along them, from Yorkshire to South Devon, and say, 'there! is not that a country worth living for, and worth dying for, if need be!'" My readers will admit the fidelity of this charming description, and long to find themselves again on the Welsh Borders.

My first actual acquaintance with the country west of the Malvern Hills began August 29th, 1864. I was then a schoolboy, and was paying my seventh visit to Malvern, and that day, a singularly lovely one, I strolled to Ledbury, delighting in the dense shade of the road between Colwall and the town, and returning over the hills in the evening. Since then good fortune has enabled me to stay at Ledbury, Hereford, Madley, Turnastone, Ross, Lydbrook, Abergavenny, Brecon, Usk, Chepstow, Llanmartin, and Cardiff, and in this way I have gone through many of the fairest parts of England and Wales. If it came to choosing a place, beautiful in itself, with exquisite country near, and admirable railway facilities, a place where a little money goes a long way, and which soothes and invigorates the town dweller, I know nothing easier; perhaps the difficulty is to select the best out of twenty equally good. Any of the places mentioned are admirable for the purpose. The rural seclusion, the scanty population, and the total change of life, are just what the worn and worried business man needs during his short holiday, nor is there any lack of places of special interest to give some prominence to excursions. Let me begin systematically. Ledbury is quiet and small, but its orchards and verdure are not easily matched. Near Ledbury there are some interesting ruins, and from Ledbury the twelve-mile walk to Ross, is very beautiful and abundantly diversified; I have done it in heavy rain, there and back, and found it delightful. A few miles from Ledbury is Bosbury Church, with its huge, square, detached, donjon-like bell tower, ruder than that of Ledbury Church, but more massive. Then the walk to Dymock and Newent is, to say the least, pretty. Hereford of course is a fairly large town, with a Cathedral that offers a good deal to interest one in the shape of a singular, open-work, central tower, and a remarkable map of the world, the latter, by the way, more curious than accurate or beautiful. Ross is a prosperous place, famous for its Horseshoe Bend and for the beautiful road to Hereford, fifteen miles off, with a view at Much Birch, that, at five or six on a bright August evening, amply repays for any trouble to get to it. Lydbrook is dingy and smoky, but is situated in lovely country, and is reclaimed from neglect by its lofty viaduct and tapering supporting piers, 200 feet high, thrown right across the narrow valley, and resting in the garden of my accomplished friend, Dr. Theodor Linde. Symond's Yat is famous for its precipitous rocks, and—in a dry October—for rich foliage recalling that of America.

The Forest of Dean with the handsome Speech House, on the one hand, and Goodrich Castle, on the other, are close to Lydbrook. Chepstow, too, with its viaduct, high tides, massive castle, and proximity to Cærwent and Tintern, and deep, mossy, shady valleys, has much to recommend it. Monmouth, moreover, with its lofty church tower, and traditions of Henry V. must not be passed over, nor Usk, with its castle; nor Cardiff, with its castle and the tastefully restored Cathedral at Llandaff. Nor must Abergavenny, with its castle and charming walks, be omitted. Lydney, also, with its tapering spire and famous bridge, is worth a visit; and then, what of Llanthony Priory, perched on the side of the hill a few miles from Llanvihangel. Never have I seen a fairer sight than that which opened before me, as I crossed the Black Mountains in September, 1887, and wound down the footpath into the valley, with the remains of the vast Priory standing up superbly in the dazzling sunlight. To the antiquary the Priory is particularly interesting, as the columns are without capitals. From the ruins along the valley to Pandy station, is a walk that made me feel that one such day would amply repay for many worries, vexations, and disappointments.

Hereford, though my readers may be surprised to hear it styled a Health Resort, abounds in convenient lodgings, and can be used as a good starting-point for innumerable pleasant country rambles and short excursions along the banks of the silvern Wye. An excellent plan is to set off by a convenient train soon after breakfast, for four or five hours, and, again, about the middle of the afternoon, getting out, according to the capacity for walking, four, six, or eight miles off, and then rambling home. But I must confess that the attention is much more strained walking along strange roads, so that while the interest of the stroll and the pleasure derived therefrom are much greater, distances also seem far longer, and a walk of ten miles tires as much as a more familiar one of twenty. One of W. H. Smith's reduced Ordnance Maps is invaluable, and, after a little practice, nothing is easier than to find one's way by its help with very fair accuracy and directness. Hereford has exceptional advantages of railway accommodation; lines go direct to Gloucester, Ross, Abergavenny, Brecon, the Golden Valley, and Shrewsbury, and in summer very cheap tickets are issued to Ludlow, the Dinmore Hills, and other places of interest.

Ludlow, between Hereford and Shrewsbury, is a charming old town, with a certain far-away resemblance—in the matter of its houses—to Totnes and Chester, in other respects, nothing presents a greater contrast than the lofty hill on which Ludlow stands, and the peeps caught on every hand of undulating country, and the busy and dingy streets of Chester more particularly on a foggy evening. The principal feature of Ludlow is its castle, a noble, well-preserved pile, once of great military importance, and splendidly perched above the river. It almost makes one shudder, in these days when we so greatly prize fresh air and dryness, to think of living in the damp, mouldy, sunless vaults in which so many of the inmates of our ancient castles once dwelt. At Ludlow Castle, John Milton for a short time lived and wrote, and within its shelter Samuel Butler got through some of his best work, while Richard Baxter found here a resting-place. The Norman Chapel, a circular building of singular appearance, calls for careful examination. It was built by the Knights Templars, and resembles in appearance and design many churches which owned their sway. Four other circular churches remain in England, of which the Temple Church, in London, is the finest, though let me say that it is the circular portion of the latter which dates its foundation from mediæval times, and not the large and imposing nave, which is far more recent and, architecturally, less interesting. Ludlow Round Church once had a beautiful round steeple, and is remarkable for fourteen niches inside. The entrance is Norman, and of singularly beautiful workmanship. Ludlow would not be a bad place for a quiet summer holiday; it is large enough to have plenty of newspapers and postal deliveries; very easy of access, aud beautifully situated, and with no dearth of comfortable accommodation, the last a matter of importance to the visitor, but one in which in the open country a stranger is often grievously disappointed, and he finds that although the country may be charming and the cottages picturesque to a degree, he must be satisfied with looking on them from a distance.

At Hereford we are not far from the lovely scenery so exquisitely described by Wordsworth in those familiar lines, the full force of which only strikes us as we wander along the stream. I transcribe the passage, which gains in interest every time it is perused.

"Five years have passed; five summers, with the length
Of five long winters; and again I hear
These waters, rolling from their mountain springs
With a sweet inland murmur. Once again
Do I behold these steep and lofty cliffs,
That on a wild, secluded scene impress
Thoughts of more deep seclusion, and connect
The landscape with the quiet sky.
The day is come when I again repose
Here, under this dark sycamore, and view
The plots of cottage ground, these orchard tufts,
Which, at this season, with their unripe fruits,
Are clad in one green hue, and lose themselves
Among the woods and copses, nor disturb
The wild green landscape. Once again I see
These hedgerows, hardly hedgerows, little lines
Of sportive wood run wild; these pastoral farms
Green to the very door; and wreaths of smoke
Sent up in silence from among the trees!
With some uncertain notice, as might seem,
Of vagrant dwellers in the houseless woods,
Or of some hermit's cave, where, by his fire,
The hermit sits alone.
These beauteous forms
Through a long absence, have not been to me
As is a landscape to a blind man's eye:
But oft, in lonely rooms, and mid the din
Of towns and cities, I have owed to them,
In hours of weariness, sensations sweet,
Felt in the blood, and felt along the heart,
And passing even into my purer mind
With tranquil restoration: feelings, too.
Of unremembered pleasure; such, perhaps,
As may have had no trivial influence
On that best portion of a good man's life,
His little, nameless, unremembered acts
Of kindness and of love."

Sometimes at Hereford the tongue of the ancient Cymry is heard, and in the streets, shops, and markets, many countenances are noticed, that proclaim Welsh descent. But to see the Welsh, and hear their tongue to perfection, we must go further west. My first visit to Brecon, six years ago, will not soon be forgotten. A friend urged me to go over, but being an old military man—indeed it was the present honorary secretary of the Woolhope Club, Mr. H. C. Moore—he did not fall into raptures, but in a clear, decided voice remarked, "you had better go to Brecon; the town is poor, but the country round pretty." And so I went. The afternoon was all I could desire—warm, cloudless, and the days still long; it was

the 5th of August, 1882. On leaving Hereford, I was not at first particularly struck by the country, though it certainly was very pretty, but after a few miles the railway wound along a broad, deep valley, bounded by distant, but richly wooded hills; in the hollow of the valley wandered the broad, but shallow Wye. For miles there was a succession of panoramas, seen under circumstances of exceptionally good fortune, and far more lovely than even the beautiful valley stretching from Chepstow to Monmouth. The clearness of the air, and the fashion in which the houses, churches, and towns were perched on the heights, made the excursion very attractive. Brecon is old enough, poor too, and abounding in very squalid, and shall I dare to add unsavoury Welshmen and Welshwomen, but withal kindly and obliging, and imbued with a deep religious spirit. Three times since I have passed along the valley under similar conditions of brilliant sunlight and refreshing verdure, but I must confess that Brecon is a mountain town, and has the disadvantages of such a situation—in other words, far more cold than warm summer days, and a fatal propensity to pour down rain in torrents most unexpectedly on the traveller's head, so that if it is a mere matter of the greatest number of hot, sunny hours, and rainless days, Hants and Dorset have far greater advantages, but they cannot compare with Brecon in verdure, shade, and picturesque effects,

The town of Brecon, in spite of poverty, has much to recommend it in its situation. It was the birthplace of Sarah Siddons, and that is enough to invest it with interest in the eyes of lovers of the drama; then it has a noble Priory Church—S. John's—in admirable preservation, and with English and Welsh services. The grounds of the Priory, open to the public, through which the beautiful Honddhu ripples, are on a sunny summer day unapproachable in their leaf tints. From the winding walk, a hundred, and in places two hundred feet above the little noisy stream, you look down on the lofty trees below you, insecurely perched in the sides of the steep bank; and instead of looking up at the different tints, as one is commonly obliged to do, here we look down with a singularity of effect that to most English people will be quite unfamiliar. Brecon is called Aberhonddu by the Welsh, from being at the junction of the Usk with the Honddhu, rivers that for picturesque scenery leave nothing to desire. At Brecon, Welsh is commonly heard, and many of the people speak English with difficulty; and occasionally some are found in the market, and still oftener in the direction of the Beacons and towards Devynock, who neither understand English nor speak it. The Brecon Beacons, three noble hills, five miles from the town, are of singular grandeur, the loftiest rises 2,930 feet above sea level. I have twice reached the top, and on days of great beauty, but, as is usual in England, the view at that height, even in the most favourable weather, was obscured by a thin film of haze, which greatly impeded distinct vision. The Falls of Ffrewgrech, on the way to the Beacons, are very pretty, especially after heavy rain, when the water descends in sheets. Llangorse, or Llyn Safaddan, six miles in the other direction, towards Hereford, is also charming, a vast sheet of limpid water, three miles long and one and a half in width. One of the prettiest excursions is to Talgarth, and another to Builth Wells, along the rocky valley of the Wye, about twenty miles, and then across the hills, fourteen miles to Brecon, at first rich and fertile, then bare, bleak, and savage, with generally a keen wind, which even in summer is biting, and, finally, rich and verdant again to Brecon. An excursion to Devynock remains, along the road past the gaol, for ten miles, to which I must direct special attention—a walk that for beauty, variety, and picturesqueness has not many rivals.

Herefordshire is singularly beautiful for its woods, rivers, meadows, hills, and verdure; it is bewitching too in other ways—in a dreamy far-away life, in its seclusion, and in the survival of old world manners and traditions. Besides, it is a borderland, partly Welsh, partly English, and constantly obtruding its dual character on the visitor. This gives it special interest to those whose fancy wanders by preference to other days and primitive people. Between Herefordshire and Middlesex, or the neighbourhood of Manchester, what a vast gulf intervenes, which the few miles of railway do not bridge. So there are many reasons for regarding Herefordshire as a pleasant land, one in which a summer holiday can be passed with profit by a lover of the country.

Is there a lovelier sight than an orchard laden with golden fruit, at that season when the rapidly shortening evenings and the falling temperature warn that the short, uncertain summer of our high northern latitude is approaching its close? Yes there is a still more beautiful sight—an orchard in the soft, mild climate of the West, at the beginning of May, when every spray is covered with delicately tinted white blossoms, and the promise of the year trembles in the balance—a sharp night's frost, a stiff gale and the blossoms are cut off, and the ground strewn with withered leaves, tells the gardener that his labour and thought will have no return, and that he must be content to wait another year. In the rich retentive clays of Herefordshire and Worcestershire the hedgerows, gardens and orchards groan beneath their beautiful burden in a mild September, and it is tantalising to think that those golden spheres, fair as the apples of the Hesperides, are, like Dead Sea apples—beautiful and tempting to the eye, but bitter and sickening to the taste. Were the skies serener and the temperature higher, September on the Welsh Borders would leave nothing to desire: unfortunately the black clouds, the driving rain, and the chilly air make one long for lands, where the Heavens wear a more smiling face and the pinch of cold is not felt so early.

In the following pages I have tried to describe the salient features of the Valley of the Dore, a district seldom visited and still little known—that part of Herefordshire stretching from the ancient cathedral town towards Abergavenny, and interposed between the Black Mountains of Monmouthshire, with the often talked of but rarely explored ruins of Llanthony Priory, and the Valley of the Wye, often sung by poets.

But first of all let us ask the meaning of this suggestive word Dore. It is stated to be a modification or derivative of Dwr, water, a not inapplicable name, which was in the Middle Age confounded with the Latin and French for Gold, and that error has been perpetuated in the modern name—the Golden Valley.

The Golden Valley!!! What sweet music breathes in the words! It recalls scenes of rural felicity and peace unfamiliar to the busy dweller in crowded and unlovely cities, scenes of quiet happiness, which soothe the heart, and make it confess that life *is* worth living and that nature *is* most beautiful and beneficent. On one of those glorious summer afternoons so rare in England, but when they do occur more exquisite than anything which the rest of the world can show, is the time to see the Golden Valley to perfection. Then the traveller from Abergavenny to

Hereford passes through a country displaying everything most characteristic of English landscape—extensive woods, deeply-green grass fit to adorn a King's lawn, and gently ascending hills, sufficiently low to be verdant and fertile to the summit, but lofty enough to invest the landscape with a sort of mountain character. Of late years I have often visited the Welsh Borders, sometimes extending my excursions far into the heart of the principality, but generally remaining near the dividing line, and I have come to the conclusion that, taking that Border land as a whole, even England, the prettiest land under the sun, has nothing more charming. Often when far away my thoughts go back to those quiet woodlands and rich valleys, which, once seen, make an impression that lasts as long as life. One brilliant Saturday afternoon, in July, 1886, after a long spell of broken and stormy weather—having wandered about picturesque Abergavenny in the earlier part of the day—I got out of the train at Pontrilas, the Junction for the Golden Valley Line, and thus made my first acquaintance with a part of Herefordshire, which, previously unfamiliar to me, I have since been fortunate to visit many times in bright sunshine and in dark cloud, in warmth and in comparative cold. As sometimes happens in our humid climate—though it must never be forgotten that to that coolness and humidity we owe our unsurpassed verdure—the afternoon on which I first saw the Valley of the Dore had become cloudless, while the rain of the preceding week had thoroughly cleared the air and freshened the foliage. Every object stood out distinctly and sharply, and as the train dragged its weary length along the Valley, it would have required little effort to fancy that the eye rested on the Happy Fields of the Blessed. Never since that afternoon have I passed along the Valley with nature and weather in such perfect concord, never have I again seen such a clear sky, nor have I experienced so genial and invigorating a temperature; indeed my first visit was paid on one of the six perfect days, as Lord Lytton happily called them, of an English summer.

Roscoe, in his charming work on North Wales, thus feliciously described his expedition into the district.—"From Moccas Park, crossing the brow of the intervening hill, we are tempted to descend into the far-famed Golden Valley, whose luxuriant vegetation and gay yellow flowers well deserve such a fairy tale name."

It was soon clear that whatever the charms of the country, the railway service left much to desire. Only three trains a day each way, and, fortunately perhaps for the tourist, their speed would not alarm a respectable stage coach. The engine is unmistakably ancient, and goes wheezing along in strange fashion, while there is a curious nonchalance in the manner in which the passengers are looked after that makes one confess that in Sleepy Hollow time is of no particular value, and if the train is forty minutes late reaching Dorstone, the quiet terminus of the line, or stops to pick up passengers, or puts them down by the wayside, no one will complain. The little shaky train once actually halted to allow the passengers to watch a cricket match, and on another occasion a party of Golfers was taken up not exactly at a station. But the courteous secretary of the line assures me that no one need complaim, for one train actually runs through at the rate of twenty-two miles an hour, when not delayed that is, and after the opening of the extension to Hay, which is shortly promised, everything will be improved, and trains will not be shunted as now, nor will delays be so many and wearisome. Well, so be it, always provided that the good time coming does not destroy the character of the valley, and although developing trade lead to the sweeping away of that quiet beauty which invests the Golden Valley with peculiar charms. A few weeks ago, when at Hay, I noticed to my dismay that the extension to that town was rapidly approaching completion.

Perhaps it will be better to describe the valley systematically and to approach it along the noble high road from Hereford, the busy and flourishing old city, which continues to be the centre of shopping and marketing for the South Welsh borders. Passing from Hereford, over Wye Bridge, not forgetting to look up and down that beautiful stream, and taking the Peterchurch-road there lies before us a vast plain—the Wye Valley, verdant and fertile, abounding in well-grown timber, splendid orchards, and carefully cultivated fields; a country worthy of the enduring memorial, which the lamented Dr. Bull, of Hereford, built up in the Herefordshire Pomona, one of the noblest contributions to scientific fruit culture that ever came from any pen. For some miles nothing of importance except the graceful tower of Belmont Priory, presents itself, and the country continues to be a reproduction of much of Salop, Worcestershire, and Gloucestershire. At last the eye rests upon the square and massive tower of a huge church to the left, and in a few minutes a vast pile comes into sight—the majestic church of Madley. Like most very large old churches, it is vulgarly called an abbey, but has no claim to that distinction, nor to that of priory; it is simply a parish church, which had at one time an extensive establishment of chantry priests. On entering the sacred building one is surprised, not only by the size of the interior, but by its perfect architectural proportions, and the exquisite taste with which it is maintained. A glance shows that Mr. Edgar Pratt, the vicar, is proud of the glorious edifice with whose charge he is entrusted, and that he lavishes upon it that loving care, which only a man of culture and refinement could give it. One cannot help regretting that such a spacious building should be hidden in a tiny village, in a district, where, as is the rule on the Welsh Border, most of the inhabitants are Nonconformists and the reverse of friendly to the Established Church, and that a pulpit orator of such impressiveness as the genial and accomplished vicar should preach to half empty seats, when many large towns have to put up with inferior churches and indifferent preachers. Looking towards the altar or communion table there is, on the right, a side chapel of magnificent proportions, and equal in dimensions to many a large parish church; the chancel is also large, and terminates in a splendid apse. Under the chancel a grand crypt, in excellent preservation, lies concealed. High Wycombe Church is a noble building, and is said to come eighteenth on the roll of English parish churches as regards size; Madley Church strikes me as being very little smaller, so that it would probably rank somewhere between twentieth and thirtieth. Beyond Madley, which is a little over six miles from Hereford, the country rapidly becomes broken, and before long a line of picturesquely wooded heights is seen, the northern or north-eastern boundary of the Golden Valley. Two ways lead to it—a fairly good road to the left, which turns out of the middle of Madley, at right angles to the high road, and makes a wide detour, reaching the valley at Vowchurch, or the main road from Hereford to Hay can be followed for two miles beyond Madley; it should then be quitted, and the tourist should turn sharply to the left, and go straight to the foot of the hills, and climb the steep ascent of Stockley. If the former be taken, the character of the country alters very little; there is the same succession of magnificent

hedgerow and park timber, narrow winding lanes, immense orchards and lawn-like meadows, which never lose their freshness in the driest summer, although South Dorset may be brown and bare, and dust may be lying an inch thick in the roads there. The deep, tenacious clay of Herefordshire and the frequent showers preserve the beauty of the landscape however much other districts may suffer, and Dore Valley, from its situation among the hills, has no cause to complain of dearth of water; even in the summer of 1887 there was nothing approaching a drought. Should the first route be chosen, that passing the west front of Madley Church, it would be better to make a little detour to St. Kilpeck, a famous and singular Norman church near the Abergavenny and Hereford line, and close to St. Devereux. St. Kilpeck is a gem, not distinguished for size, but for its splendid preservation and the little injury it has sustained at the hands of church restorers, who have been content with piercing a fresh window, admitting more light and not greatly disfiguring the edifice, though not in harmony with the original design. St. Kilpeck is small, and stands at a little distance from the high road, in a field indeed; on approaching it, the singular beauty of the south doorway with its rich carving arrests the attention. The body of the church is massive and imposing, but the finest effect is from the west; looking to the altar the eye rests with peculiar satisfaction on three perfect concentric arches, the largest at the entrance to the chancel, the smallest near the east window. The chancel is most beautiful, and the massive Norman walls and small windows are in keeping with each other. The exterior of the church is fine and imposing, and adorned with lovely tracery, and shows little signs of wear; indeed, for all one sees, St. Kilpeck may last many a century longer to show our descendants how well the Normans did their work.

Retracing our steps to Stockley Hill, six or seven miles from St. Kilpeck and ascending to the summit of that steep ridge, we, before long, reach a spot where the road rapidly begins to descend, and half-an-hour takes us into the middle of the Valley near Peterchurch. Just after passing the top of the ridge, if the atmospheric conditions are favourable, the eye catches exquisite glimpses up and down the valley, and even over its southern boundary into the Black Mountains, towards Abergavenny, in the one direction and Brecon, with its three lofty Beacons, in the other. Peterchurch, a pretty little village, with nothing stirring, does not delay us long: the railway station, for it actually boasts of one, is seldom busy, and the offices of the kind-hearted Secretary of the Golden Valley Line are so little conspicuous for crowds of business callers that one hardly wonders that it does not pay to run trains at higher speed.

The Valley, stretching a dozen miles fron Pontrilas to Dorstone, has nothing remarkable beyond the lovely scenery, which I am attempting to describe, except three churches of more than ordinary importance:—Peterchurch, Vowchurch and Abbey Dore, of these more anon. At present a few words are called for about the peasantry, who form the mass of the population: Many have an unmistakable Welsh accent, although few bear Welsh names and none understand Welsh; most indeed have never been in Wales, though living on the borders of the land of the Cymry. Professor Freeman has happily pointed out that the people of many parts of Wales, for example near Tenby, are not Welsh, but I do not think that he draws attention to their not admitting that they are Welsh. One day near Llanthony I asked a labourer, whose strong Welsh accent left his birthplace in no doubt, if he was Welsh, "No!" he replied very good naturedly, "I am not Welsh, I am a Radnorshire man born and bred. You must go to Brecon and Talgarth for Welshmen." At Builth, in Radnorshire, however, notices are still printed in English and in Welsh, and sometimes in the latter alone, which is somewhat inconvenient to strangers.

Wages are painfully low, not more than ten to twelve shillings a week, and the standard of living is deplorably poor. This is partly due to the absence of resident wealthy families, partly to the want of trade and enterprise. It distresses one to notice that in districts where nature has been so lavish, the inhabitants are often poor in a degree, and that resident families of consideration are seldom found. Many of the gentry of this part of Herefordshire have suffered severely from the agricultural depression, and at best the possession of a small estate of 800 to 2,000 acres, if heavily mortgaged, as is often the case, is no great matter from a money standpoint. The unhappy Squire, reputed to be rolling in riches, and with a good county position to keep up, knows that an income of £400 to £600 will not do much, although he may be the envied master of an ancestral hall and a well-kept park. The Golden Valley would gain by the arrival of a dozen families of means. Why do not more of the well-to-do classes, who are tired of large towns and anxious to enjoy life in one of the most charming districts of England, find out the Golden Valley and make it their home? The cottages are falling into decay, and there is an air of squalor among the peasantry reminding one of Brecon and other Mid-Wales towns. Different types of people present themselves and the curious visitor sees traces of successive waves of population.

Peterchurch or Llanpeter, still the most important place in the Valley, was, my friend the Rev. Willis Lambert, the Vicar, tells me, the seat of large iron works, employing 200 men a couple of centuries ago: a mound is all that remains of this past magnificence and importance. The church from the outside only strikes one as large and massive, with a square tower, surmounted by a lofty but not particularly beautiful spire, which is, however, a conspicuous object for a long way round, and sets off the scenery, although lacking the graceful tapering proportions of St. Andrew's at Worcester. It, nevertheless, from a distance, where the eye cannot perceive its want of ornament, is an object one would regret to lose. The interior of Peterchurch is singularly impressive: smaller perhaps than one expects from outside inspection, but in admirable preservation and reverently kept. Looking towards the altar the same succession of massive Norman arches and the same splendid chancel as at St. Kilpeck offer themselves, although the church is plainer, the carving inferior, almost non-existent, and there is a scarcity of beautiful tracery and no imposing doorways.

From Peterchurch the route is easy to Vowchurch, the next station towards Pontrilas. Here an unexpected treat awaits us. When the visitor reaches the church he sees a plain, unpretending little building, with no lofty tower, grand porches or superb chancel, indeed from the outside a common place old parish church, one of that large class most suitable to thinly inhabited districts, but which can be seen in five thousand other places. Fortunately my kind friend Mr. Pratt, of Madley, had prepared me for what made Vowchurch unique, so that on entering the unpretending door I looked round with astonishment. The building contains a number of stupendous cross beams and uprights, looking something like the framework on which the sides of a large wooden house might rest. The wood

of the beams is dark and has evidently seen long service, but promises to last many a year. The curious part of the matter is that the walls and roof do not seem to rest *upon* these tranverse beams. Unfortunately the Vicar, my friend, Mr. Bevan, a man of superior intelligence and naturally proud of his singular church, could give me no explanation. No record, as far as curious and repeated inquiries disclose, exists of the time when the beams were put together, nor of the reason why they were erected. The first impression is that these beams and uprights were the framework of a large wooden church, and that the sides, having become unsafe, were removed, and a casing of stone substituted. But the wooden skeleton can hardly go back three or four centuries, and yet in less time all record would not have been lost of their erection. Stone must always have been abundant in the district, and rude stone walls would have been as cheap as wooden ones. It is a mystery, and I cannot solve it, though probably the information could be found, did one only know where to look. Two other churches somewhat similar to Vowchurch exist, or till recently existed, but I am unable to say anything about them. One is said to have been pulled down, and the other, a clerical friend, who has seen it, tells me, is very little like Vowchurch, so that I must come back to the point from which I started and repeat that this church is practically unique and worthy of a visit.

On the other side of the Dore, not more than a bow-shot, there is a low, solid and unpretending church—Turnastone; it too is of great antiquity and dates from remote Norman times. From Turnastone or Abbey Dore, the distance is trifling to Llanthony. Starting from the former, which is the more distant, the road rapidly ascends a low range of hills to Michaelchurch, and then makes a sharp bend to the left to Longtown, from which a good bridle path ascends by easy zig-zags to the top of the Black Mountains, and then rapidly descends leading direct to the beautiful remains of the Priory Church, which on a bright sunny day, can be distinctly seen at the bottom of the Valley, projected against a background of fine timber. The Priory has many remarkable architectural features, in addition to its glorious site, the most notable, as I have said above, being the absence of capitals to the pillars. From the ruins, which are admirably kept, to Llanvihangel Station is little over an hour's walk, and in fine weather the scenery is exquisite. Though the distance from Turnastone to Llanthony is small it is not easy to find people who have gone from the former, or *vice versâ*, and even the Golden Valley clergy talk of Llanthony as being far, far away, over the mountains, quite in another world.

Another grand ecclesiastical building remains—the transepts and chancel of Dore Abbey. This church stands half way between Pontrilas and Vowchurch, in the midst of the same characteristically English scenery. The second time I saw it I started on my journey from Peterchurch station. The Golden Valley train waited a quarter of an hour at Vowchurch to take breath, and on approaching Abbey Dore Station another delay occurred. As my time was limited I descended and walked along the line to the station, where I gave up my ticket to a most obliging official, who regarded my proceedings as a matter of course. Then I wended my way to the Abbey wondering how long this primitive manner of managing a railway would continue. Arrived at the Abbey I was struck by the background of woods and hills, which made it unique, as every grand natural scene almost necessarily is. On entering the church I noticed that only a small part of the once vast whole remained—a splendid chancel with retro choir and spacious aisles, and two transepts, the last greatly in need of restoration. Strenuous exertions are being made to collect funds for the restoration of the Abbey Church, including the building of a nave in keeping with the rest of the edifice, but as not less than £40,000 would be required, there is small chance of success. The nave is entirely gone, and some authorities doubt whether it was ever finished. Examining the west wall of the transept one sees that a vast arch has been filled in with masonry as though, at the demolition of the nave, the remainder of the edifice had been adapted to divine worship and made air and water proof. Moreover, in a line with the choir there are, at what must have been the commencement of the nave, two huge squat pillars, in splendid preservation. There they stand in the open air, the remains of the demolished nave, or the commencement of a stupendous work never completed; who can decide?

Recent explorations are said to leave no doubt that the nave was built and completed, though history holds no record why and when it was dismantled. Two hundred years ago this grand old church was a roofless ruin, and was put into decent condition by the Viscount Scudamore of that day. He also built a lofty tower, surmounted by a small steeple, in the corner between the chancel and the south wall of the transept; this addition is handsome, but not in harmony with the rest of the architecture: moreover it ought to stand at the crossing, or intersection of the chancel and transepts. On leaving Abbey Dore one cannot help wondering that a valley so remote and so much exposed to Welsh incursions should abound in ancient ecclesiastical buildings. It is wonderful indeed how rich many parts of the land continue to be in churches and castles, in spite of the ravages of time, fire, war and Vandalism. It must have struck many persons as singular that in the baptismal service the officiating clergyman is directed to immerse the child, unless the parent certify that it is too feeble to bear the shock. Probably few people have seen a baby immersed, and most churches have not a font of sufficient magnitude to make immersion practicable. It is interesting, in certain Herefordshire churches, to find a huge stone font so large that there would not be the smallest difficulty immersing a child two or three years old. One of these survivals of the past is in Madley church, another at St. Kilpeck, and a third at Abbey Dore. Of course infants are not now immersed, and the water for baptism is placed in a small vessel standing in the immense font.

The whole valley abounds in ill-defined remains of camps, four and five being found in a single tiny parish, but all small and uninteresting, and some require sharp eyes and a glowing imagination to detect after they have been pointed out by well-informed natives; as a rule the inhabitants are not well-informed, and are reserved and dull, painfully less intelligent, worse educated, and not so prosperous and self-reliant as the members of their own class in south-east Dorset, whose condition has no doubt been greatly influenced by the rise and growing importance of Bournemouth.

Retracing our steps to Peterchurch, and following the north side of the railway as far as Dorstone, at present the terminus of the little line, and turning sharply to the right, let us follow the road to the summit of the elevated and commanding ridge near Arthur's Stone and Meerbach. Every step unfolds fresh beauties, and if the day is clear and sunny, glances backward show the valley under most

favourable conditions, with peeps far away into Monmouthshire and Breconshire. The ascent is not very abrupt nor long, moreover for miles along the Dore Valley the road rises towards Dorstone. When the top of Meerbach is reached we are at a much greater elevation above the Wye than we expected. On the top of Meerbach, a little way from the high road, there are some fine stones, which the late Rector of Dorstone counted to the number of thirty or fifty. They are not very large, and some have been removed, and others broken up, but as they are prehistoric remains they possess a good deal of vague interest for the antiquary, and repay a special visit. The little intercourse between the Golden Valley villages almost taxes one's imagination. I am assured that some of the inhabitants of Peterchurch have never wandered as far as Vowchurch, a distance of two miles, and still regard the people of the latter as semi savages. One day this summer I took a friend's carriage from Turnastone over the hills to Timber Lines and Stockley, and found that I knew the country far better than the groom, who told me that he had never been outside the Golden Valley before, except by train to Hereford. Two years ago, at the time of the Colonial Exhibition, Mr. Aubrey Taunton and Mr. Powell, the present Rector of Dorstone arranged an excursion to Town, taking with them 1400 of the natives, the adventures of the latter were innumerable. Mr. Powell has an amusing trick of walking with his hands under his coat tail pockets, gently agitating that part of his clothes. Suddenly in the middle of Piccadilly he noticed fourteen of his parishioners walking as he was walking, they stopped when he stopped, faithfully imitating his movements. After a time they invaded a jeweller's shop to buy eighteen penny gold bracelets and chains for their wives and daughters, somewhat to the consternation of the shopkeeper. Near the Mansion House their patriotism was outraged by the want of good manners of the city police, who did not touch their hats to Mr. Powell, although he is a Herefordshire magistrate. This led to a good many comments on the part of the Golden Valley men and to some audible murmurs on the bad manners of the Metropolitan police, which the latter showed some signs of not taking in good part. One of the excursionists was lost, and was actually picked up on Westminster Bridge. At last, after an absence of twenty-seven hours, the party returned safely to their homes, very tired and with much to talk about for many a long year.

Looking from Meerbach across the picturesque valley towards Hereford, if the atmospheric conditions are good, the scene is one of such beauty that even the Welsh Borders have few superior. Descending the slope towards Bredwardine and Moccas, the same exquisite landscape continues, but with few features of special mark. It is generally admitted, and much regretted, that the gleam of water is rare in English scenery, and so it is with unwonted pleasure that, suddenly, we reach a spot where, a few miles off, we see the Wye directly before us—a silver streak in an ocean of verdure, and projected upon the water the outline of a few tall trees can be made out. Then we gradually descend, and as we continue our onward course the plain is seen to be more broken than it looked from the top of Meerbach. Modest elevations show themselves, and houses begin to appear. When at last we get to the main road from Hay to Hereford, though many miles nearer the former than at Madley, we turn towards Hereford; the hills to our right are seen to be clothed with magnificent timber, while the valley is carpeted with smooth turf. Before long the road reaches the beautiful park of Sir George Cornewall, and continues to skirt the hills for some miles; finally it makes a sharp bend to the left, and in due time we get back to Hereford.

BOURNEMOUTH FOR CHILDREN.

By Horace Dobell, M.D., etc.,

consulting physician to the royal hospital for diseases of the chest, london; the royal albert orphan asylum, bagshot, etc., etc.

Judging from the number of letters of enquiry which I receive on the subject of this paper, it would seem that the rising generation of doctors are not so well posted up as they wish to be on the qualifications of Bournemouth as a health resort for children. In my work on "The Medical Aspects of Bournemouth," I had so many other important matters to discuss that I did not give so much prominence as I ought to have done to the speciality of the place for delicate children; but I did say, when speaking of its freedom from "marine cachexia" in chapter iii., "The poor children to be seen in and around Bournemouth are remarkably well-developed, healthy, and good-looking—the healthiest I have seen at any sea-side place; and it is well known that Dr. West, the eminent founder of the Children's Hospital in London, was so impressed with the beneficial effects of Bournemouth on delicate children, that he established a school for them, which has for many years been a very great success." I might have added that the managers of the Alexandra Hospital for Hip Disease, London, selected Bournemouth for their sea-side branch, and that it has proved most satisfactory in aiding the recovery of these troublesome cases.

But I do not know any evidence so good as that of the Bournemouth Orphanage, to which the Sisters of Bethany in London send destitute children for care and education. The beneficent effect upon their health is wonderful. There is no prettier sight in this neighbourhood than these nicely clad children, who are to be met in troops of twenty to fifty, in charge of one or two sisters—rambling unrestrictedly through the heaths and pine-woods, or along the sea-beach—laden with country treasures, their ruddy faces beaming with health and pleasure—and testifying to the strength of their limbs and lungs by their agility in running up hill and down, and jumping over banks and bushes. I never saw a host of poor children who looked so full of joyous life as these.

Some thirty years ago there was a Dr. Mainwaring practising at Bournemouth, who made many judicious observations on its medical aspects; and I find among these the following note about children, as the result of ten years' experience: "As a resort for delicate and rachitic children it is unrivalled. The sands afford ample scope for amusement and exercise; the children dig and shape it into various forms and devices, which prove a never failing source of attraction to them; at the same time they are situated in a dry, warm playground, being sheltered by the wood-crowned cliffs. I have often been surprised and delighted by the rapid improvement that has taken place in pale and sickly children from India, and in children suffering from rickets in an aggravated form . . . The little sufferers have been changed from a state of listlessness to one of activity and comparative strength, and from the misery of fastidious appetites to craving heartiness."

Anyone who studies the specialities of the place will easily see how peculiarly it is suited for children, in addition

to its fairly, but not too mild, marine atmosphere, and extraordinarily porous, dry, sandy soil, from which it is impossible for moisture to appear again, so rapidly does it percolate beyond the reach of surface influences. The beach is absolutely free from danger, for the sea never recedes far enough to expose rocks or islands of sand from which children may find it difficult to return when the tide flows in, and there is always a broad expanse of dry sand between the "edge of the waves" and the cliffs, from which egress is safe at all states of the tide. The shore is completely protected from the north, and to a large extent from the east, by the crescentic wall of cliffs, rising about 120 feet. When the air is not fresh enough on the beach, there are fine breezy walks on the tops of the cliffs; and when these are too windy or too cold, there are the pine-woods, traversed by excellent gravel walks and roads, and easily accessible by the different chines or ravines running from the woods to the sea; or, when it is advisable to get away from the sea-side altogether, there are the lovely "Talbot woods," which still contain over one million pine trees. They are always sheltered, although permeated by sunlight, and afford innumerable safe walks, free from underwood, and always kept dry by their bed of pine needles.

But one of the greatest advantages for children is, in my opinion, the abundance of open heathland in all directions round Bournemouth, the air of which is most invigorating. The roads which cross these heaths to the neighbouring pretty villages and farms, are admirable for horse, pony, and donkey exercise, and they are made good use of now by the riding masters, with their troops of boys and girls and older pupils, who are to be met in all directions. Another feature very characteristic of Bournemouth, and fully appreciated by parents who bring children to the place, is the gardens which surround the houses. Instead of the children having to go straight out of the house into the road or street, as in most sea-side places, nearly all the best lodging-houses, hotels, and boarding-houses, are surrounded by gardens and grounds, into which the children can run with safety. Another important point is the abundant supply of unquestionable milk, eggs, and butter from the large Hampshire and Dorset farms, the dairies of which are under close medical inspection, and I see from the agricultural reports that the "Hampshire Down mutton" is now considered superior to the famous 'South Down,' both in size and quality.

Within the last year a large, well-arranged, tepid sea-water swimming-bath has been added to the institutions of the town, where swimming is well taught by experienced teachers of both sexes, and aquatic entertainments are given for the amusement of children.

I need not go further into details; those I have mentioned sufficiently indicate the peculiar suitability of Bournemouth as a health resort for children of all ages, of which the experience of the local medical practitioners is entirely confirmatory. Perhaps the most strikingly *curative* effect of the place is seen in catarrhal children—children whose parents bring with them a long record of recurrent tracheal, bronchial, and broncho-pneumonic attacks, which their doctors have got tired of battling with, so obstinately and inevitably have they returned, getting longer and longer in their stay, and less and less satisfactory in their clearing up, often consummating in an attack more severe and more deeply-seated than the rest, and more threatening in the prognosis.

Many such cases I used to send to Bournemouth with good results, during my London practice, but until I came to live here, and could watch their progress, I was not prepared for the unmistakable way in which they clear up under local influences, with a comparatively small amount of medicinal treatment. Many children and grandchildren of old patients have been sent to me with ominous warnings from their medical attendants and friends, as to the trouble they were likely to give from their frequent attacks of catarrh, and the difficulty of getting them clear of vestiges and saving them from phthisis. As a general rule, after putting them well to rights at starting, laying down simple rules for their management, and taking care that they were in appropriate lodgings, I have seen very little more of them, except to meet them galloping along the country roads on their ponies, tearing past on their tricycles, or wandering with their friends in the pine woods or along the shore. Many of those who were old enough have been placed in the various excellent schools, whose managers are accustomed to the care of delicate pupils, and they have remained term after term, without requiring more medical attendance than an occasional visit from the school doctor.

It is an unspeakable advantage to have such a health resort for young people in our Island, for there can scarcely be a more painful form of refined cruelty than to order children abroad. It is rarely practicable to carry out the order; and thus parents are made to feel that a step, which has been represented to be of the utmost importance to their children's lives, cannot be taken. And if the step is taken, it must generally be at the sacrifice of the domestic comfort of a whole family, and very often at the cost of neglecting some member of it requiring as much solicitude as the so-called "invalid." I consider, therefore, that I am discharging a public duty in thus emphatically calling attention to Bournemouth as a health resort for the young. Fortunately, I am in a position to do so without exciting the suspicion, which might attach to a younger man, of being influenced by personal interest. I ought to add, that under the head of *Bournmouth*, I include Boscombe and Southbourne on the East, and Westbourne, Branksome, Canford Cliffs, and the upper parts of Parkstone on the West, representing a coast line of over six miles.

MONTHLY REPORT ON NEW PREPARATIONS,
FOODS, DRUGS, INVENTIONS, ETC.

Bourboule Waters (Ingram & Royle).—The mineral waters of Bourboule enjoy an exceptional position, in that they contain arsenic in addition to their other ingredients; hence their great value when a mild alterative is required, or a prolonged course of arsenical treatment. The waters are pleasant to take; they are bright, sparkling, and pure. The indications for their use may be generally specified; they are particularly suitable for chronic skin diseases of a non-inflammatory type; in chronic rheumatism, and in all indurated swellings, uterine hyperplasias, they will also be found of great advantage. The waters are imported into England, and may be taken in doses of from one to three glasses per day, after meals.

Antrophors (Thos. Christy & Co.)—Under this name a medicated bougie has been introduced by Messrs. Christy and Co. It consists of a spiral spring from five to six inches in length, terminating at one end in a large ring. It

is coated with any medicament desired, the medicament dissolving when introduced. The bougies are very pliable, and so covered that the urethra cannot be injured. The original intention of the inventor was to treat gleet, and to bring the active agent into contact with the local affection, and to stretch the urethra, so as to expose any diseased follicle. The antrophors have been extensively used in America and Germany, and have been practically tested in England by one of the surgeons to St. Peter's Hospital, eighty cases being treated in this manner. One case of seven years' standing was cured by four applications. The greatest benefit has been obtained from bougies made of five per cent. thallin. In a certain number of cases the bougies failed to produce any good effect, but this was because the deep urethra had not been reached. The directions are simple. The patient should first make water, so as to flush the urethra, then the bougie, after being dipped in water, should be introduced, remaining in from five to twenty minutes. We think it advisable the surgeon should introduce the bougie in the first instance himself, and keep the patient under observation, because, as in the introduction of a catheter, the urethra has to be made familiar with the presence of a foreign body; and, moreover, the patients require instruction as to the method of introduction. In certain cases it is well to use a ten or four per cent. cocaine ointment, so as to diminish urethral sensibility. All movement of course must be suspended while the bougies remain *in situ*, and therefore they should be used at night, and the patient can retire to bed after employing one, and thus all danger of fever will be prevented. There are various forms of these appliances: 1. Urethral. 2. Prostatic. 3. Uterine. All these forms can be filled with any desired drug—as iodoform, sulphide zinc, nitrate of silver, acetate of lead, subnitrite of bismuth, etc., and they can be made of any length. They may be applied not only to the urethral and uterine canals, but to any channel, as sinuses, fistulas, etc.

Pitkeathly Mineral Waters.—We are pleased to hear that the Pitkeathly waters are becoming still more popular, and are more largely used than ever. The dietetic value of good water cannot be over-valued. Knowing the source from which these waters are derived, we can confidently recommend them. These waters can be used for ordinary table purposes, and as they are aërated, they are tonic, refreshing, and stimulating. Pitkeathly mineral waters have enjoyed a repute for their medicinal properties for over a hundred years, and have been very largely prescribed by Scotch physicians for gastric derangement, habitual constipation, sluggishness of the liver, plethora, gouty and rheumatic states.

Reviews.

Breakdown of the Hospital System. By J. Francis Sutherland, M.D. Edin.

This is a very thoughtful and suggestive pamphlet, and the author must have devoted much labour to work out the statistics which fortify his assertions. Of the facts, we may say that they are mostly indisputable; some of the inferences are more debatable. The author clearly establishes his main theory that the present hospital system has broken down, and he condemns the inadequacy of the provision for the sick poor in the great centres of population; also the system of government, which is antiquated and inefficient. The system of admission is bad: many who are in-patients should be out-patients, or treated in pay wards, whilst many who are out should be in-patients. The subscriber's line or governor's recommendation leads to a preference being given to cases which are not by any means the most deserving. Dr. Sutherland demonstrates, by carefully compiled statistics, that many, if not a great majority of hospitals, have an ordinary expenditure in excess of the ordinary revenue. This leads to an annual deficiency, which is made up by absorbing legacies or bequests left during the year, or by drawing upon the capital accouut. Not only land, but other investments, have given bad or indifferent returns, and hence the income derived from invested capital has been in many instances seriously diminished. The author, who fully appreciates the great work which philanthropy has done, contends that it cannot much longer contend with the present and prospective wants of that large section of the community whom illness places for a greater or less time *hors de combat*, and he thinks that a new departure is needful in regard to the administration of such institutions as partake rather of a national than of a local character. He strongly advocates the control of a central representative authority for districts of the country; without such a body, the wants of the community as a whole cannot be known, and adequate provision cannot, in consequence, be made for that want. Dr. Sutherland establishes by careful statistics the great discrepancies which exist in the hospital accommodation for different towns and counties, and we confess his figures are somewhat startling. Thus in Ireland the ratio of beds to population is 1 in 870, whilst in Wales it is only 1 in 2,340. In Durham it is 1 in 1,930; in Edinburgh, 1 in 410; in London, 1 in 420; in Dublin, 1 in 140; and in Leeds, 1 in 1,020. The average is about one bed to every 1,000 of population. The anomalies portrayed in these statistical tables cannot fail to strike the most casual reader. Would these anomalies exist if there was a central representative body, with powers similar to those of the Local Government Board, or of the Education Department? The cost per bed in various hospitals varies from £100 to £35 per annum. No attempt, under the present helpless and divided system of management, has been made to adjust the number of beds for a district of the country, nor to take the special circumstances of communities into consideration. The attempt which has been made by the Local Government Board to deal with infectious diseases has a decided bearing on the practicability of meeting the wants of those struck down by disease other than zymotic.

The breakdown of the hospital system is at present most accentuated in London, where, combining the workhouse hospitals with those supported by philanthropy, there is actually provision for 1 in 250; but it is stated that nearly half the wards are closed, and that the aggregate income falls short of the expenditure by £100,000. Probably, many causes contribute to this unsatisfactory result, which has its reflex in the provinces. Dr. Sutherland deals with many of these causes in detail, and then lays down the doctrine that mortalities in the main should decide hospital accommodation. He contrasts the remarkable anomalies which characterise the distribution of hospital accommodation; he recognises the fact that many of the hospitals in large towns are partly filled by people coming from rural districts, and would make due allowance for such facts. The method of admission to hospitals by lines, or recommendations, is strongly deprecated. The filling up beds with curable cases, and the practical exclusion of incurable

ones, which is so generally adopted, no doubt makes the annual report more showy, but is it fair to the applicants to establish a preference for certain classes of disease pleasing to the hospital authorities? That chronic and other genuine cases of disease are not to be cared for in our voluntary hospitals, is rather a strange doctrine to hold in a Christian community; it is not the doctrine held in France, in Germany, or in Italy, where ample provision is made for all forms of disease. Dr. Sutherland suggests that the Liverpool and Manchester workhouses are doing as great, if not a greater work, than the voluntary hospitals, and he further contends that under a better system there should be no difference between voluntary and rated hospitals.

Dr. Sutherland has made out an exceptionally strong case against the existing system of hospital management, and suggests the following means of reform:

First, and most important, would be the setting up of a *central authority* for a large area of the country—this body to be in touch with a Minister of Health, when such a necessary official is created, or other high State official.

Second, the establishment by the central authority of a *medical bureau*, where the examination of applicants for the hospitals would be conducted by practitioners of experience, and where enquiry, not of an inquisitorial kind, would be made by a body such as the Charity Organisation Society. The number of vacant beds in each hospital could be learned here daily without any trouble.

Third, the hospitals at present attached to the workhouses and poor-houses to be divorced from them, and to form part of the hospital system. These might be used for chronic and incurable diseases.

Fourth, the establishment of convalescent homes, and sanatoria in the country and at the sea-side.

With Dr. Sutherland's general views we are disposed to agree, but there are some aspects of the case which appear to have escaped his attention. Any material increase of hospital accommodation must be at the expense of the general practitioner, who already finds that he is liable to be deprived of his patients, not because they are unable or unwilling to pay moderate fees, but because they expect to obtain a larger measure of skilful treatment from the hospital surgeon or physician. It is a question whether much of the work done at our large hospitals is one whit better than that which could be done by a large number of practitioners who have not the privilege of being members of the staff of the hospital. The statistics of capital operations show that a patient has rather a better chance of recovery outside than inside a large hospital, where there is a greater aggregate of disease. Mere numbers must not in any sense be deemed a test of efficiency. It may be reasonably doubted whether the out-patient at a large hospital—who has perhaps spent a couple of hours waiting in a crowded room for his turn to have two or three minutes' conference with Dr. A. or Surgeon B.—gets really better advice than he would have from a less distinguished practitioner, who could devote a considerably longer period of time to the investigation of symptoms.

With regard to pay-wards, if instituted, patients should have the privilege, at their own discretion, of being attended by professional men who are not members of the official staff, especially if the hospital is aided by Treasury grants. We cannot help thinking that there would be a serious falling off in voluntary subscriptions if the subscribers were deprived of the control of an institution, which their generosity had called into existence and maintained. Special hospitals would probably not consent to be snuffed out, but would pursue an independent course. We should be inclined to favour hospital reform, not by increasing the scope of hospital work, or by any large extension of hospital accommodation, but rather by restricting the benefits of hospital treatment to those who cannot be equally well attended at their own homes, and this refers more especially to the out-patient department. The unhealthy competition between various charitable institutions to base their claims for public support on more members is most undesirable; the quality rather than the quantity of work done should be the test of a hospital's usefulness. The establishment of small cottage hospitals in districts where the want of accommodation is chiefly felt; a strict economy in the management of the large hospitals which fulfil a national function; the weeding out of unsuitable applicants, either because they are in a position to pay for medical attendance, or because their complaints are of a trivial character, and can be dealt with as well by the club doctor or the officers of a provident dispensary; the establishment of provident dispensaries for working men and their families, are means which might be tried with advantage before invoking State aid and State control.

We can heartily commend Dr. Sutherland's pamphlet to all who are interested in hospital management; it is a painstaking effort to solve a difficult and complex problem, and its perusal will afford pleasure and instruction to all. There are many conflicting interests to be weighed, and many points of view from which hospital management must be considered. Any hasty or ill-considered scheme of reform, would not be unlikely to substitute greater evils for those which already exist, and might have a direct tendency to encourage thriftlessness and improvidence; the doctor is already called upon to do more work for nothing than any other member of society. Dr. Sutherland has undoubtedly proved the breakdown of the existing system, and his views are justly entitled to a frank and impartial consideration.

Hunterian Lectures on Tension, as met with in Surgical Practice, Inflammation of Bone, and on Cranial and Intra-cranial Injuries. By THOMAS BRYANT, F.R.C.S., Consulting Surgeon to Guy's Hospital, etc. London: J. & A. Churchill. 1888.

THE present work contains the Hunterian Lectures delivered before the Royal College of Surgeons in June, 1888. Among some of the conclusions arrived at by the author are the following: That tension stands foremost amongst the causes of pain, and in inflammatory affections it is probably the chief pain factor; that where the causes are not inflammatory the tension to which they give rise will, if maintained, excite inflammation in the tissues affected; that the tendency of tension is to keep up or intensify the inflammatory action, and strongly to encourage its destructive influences; that—and this conclusion is so weighty that we give it in full—"that, as in wounds the slightest degree of tension is injurious, so, in their treatment, the use of the drainage tube, or due provision for complete drainage, is a point of such primary importance as to relegate to a secondary position the mode and character of the dressing which is employed, since a want of attention to the efficient drainage of a wound under every form of dressing is followed by the same result." Numerous cases are given showing the relief afforded by opening tense sheaths, dividing stretched

muscles, trephining shafts of bones, and the dental canal of the lower jaw, by puncturing a tense testicle, aspiration of joints, and by drilling and trephining for many bone diseases of both head and limbs. The severity of pain in bone disease is looked upon as a fair measure of the intensity of the tension. Cases are given showing that relief of tension may initiate a cure, even though the operation may, so to speak, only have been partial; thus we read (p. 41), "In many a large hæmatoma I have despaired of its absorbtion and a natural cure till I had withdrawn some of its serous contents and removed tension, when a rapid recovery followed. Even in large abscesses, and particularly chronic abscesses, the same result may be chronicled. An interesting case is also recorded of a medical man who tapped himself for a hydrocele with a small hypodermic syringe, only ten minims of fluid were removed, and yet the tumour gradually diminished and wholly disappeared. Though the needle wound oozed occasionally for some time, the cure is ascribed to absorbtion by the veins and lymphatics, relieved from overtension by the removal of so small a quantity of fluid. To relieve tension in the softer tissues of the body, the local application of leeches, local or general venesection, acupuncture, aspirations, punctures, and incisions, may be requisite.

Numerous cases are quoted of ostitis and necrosis resulting from contusion of bone associated with scalp wound, and the conclusion arrived at after seeing many fatal cases is "that all scalp wounds which lead down to bone should be dealt with, for at least a fortnight or three weeks, with much care; and that such cases should, if possible, be treated as in, and not out-patients, of hospitals, for that time." When local symptoms appear a free incision down to the bone where no wound exists, or a free separation of the pericranium where there is a scalp wound, always does good. A perforation sets the dura mater free from pressure and gives rest to collected matter, but nothing more. We are here warned that though the patient must have perished without the trephine, yet the merely having used it will not preserve him without every other care. If the fracture be starred, comminuted, or more than *slightly depressed*, the elevation of the depressed bone should be the rule of practice.

Chas. Atkin, F.R.C.S.

A Personal Narrative of the Euphrates Expedition of 1884. By William Francis Ainsworth. 2 Vols. Kegan Paul, Trench and Co. 1888.

Nothing is more touching than the untiring energy with which some men continue to work hard until old age, with all its attendant infirmities, is actually upon them. Dr. Ainsworth took his medical diploma sixty-one years ago, and has been busily engaged ever since, for a time in medical practice, but chiefly, we believe, in literary work. He was for many years editor of the once famous Colburn's "New Monthly," succeeding his cousin, Harrison Ainsworth, the great novelist. Now we find him giving the world a most lively, readable and scientific narrative of the famous expedition in which he played a leading part, and to which he acted as surgeon and naturalist. It is sad in reading a list of the officers connected with that memorable expedition to observe how few survive—at least eleven are gone to join the majority, while only four remain. We believe that no other complete history has appeared, and the present is actually the first that covers the whole ground traversed by the explorers. To most readers the name of Dr. Ainsworth must be familiar. We may say that these handsome volumes contain many allusions to subjects on which few men are so competent to speak. We cannot pretend to review a work that would demand for the purpose the limits usually allowed by the *Edinburgh* and the *Quarterly*: all we can do is to say that the style is graphic and readable, the anecdotes are charmingly told, the scientific details full and accurate, and the description admirable. Such a work splendidly crowns the long and distinguished career of the writer, and proves that to the end he preserves the indomitable energy and light heartedness which must have distinguished him during the years when he faced fever, danger, and a fierce climate in his love of adventure, and his desire to lift the veil from the Euphrates district. Explorations are not to be lightly entered upon, especially in rude, dangerous and sparsely inhabited countries. The adventures of Mr. Charles Augustus Murray, among the Pawnee Indians of the Far West, about the same time as Dr. Ainsworth was engaged elsewhere, are a case in point: Mr. Murray had to face dangers of climate, exposure to heat, wet, and dirt, and the assaults of noxious insects, to say nothing of bad and insufficient food. Dr. Ainsworth fared no better—fever and insects plagued him exceedingly, and the obstacles which he and his companions had to surmount would have daunted most men. A particularly valuable part of the work is the appendix containing a great number of admirable antiquarian, historical and scientific comments, which do the learned author great credit, and display vast stores of information, indeed some of them, brief though they are, represent the thought of years, and could only be written by a scholar of eminence, and of untiring perseverance. Some of Dr. Ainsworth's notes on Oriental diet and cooking are particularly interesting, and we have ventured to make free use of an account of a Persian luncheon in a long article on "Dietetic Eccentricities," which we are contributing to one of the larger reviews. We are very glad the historian of the Euphrates expedition is a member of our own profession.

An old Oxonian.

Short Notices.

Suggestions for a Plan of taking Notes of Medical Cases. By George F. Duffey, M.D. Dublin.

Dr. George F. Duffey has compiled in a brief and handy form a plan for taking notes of medical cases, which should prove useful alike to the student and the practitioner. Of course, in a large practice, it would be hopeless to attempt so complete a system of taking notes in the vast majority of cases, but a careful study of the suggestions, and a frequent reference to them is quite practicable, and would tend to a more methodical and systematic examination of patients than commonly prevails. The manner of arrangement is natural, and considering the small compass, the suggestions are remarkably complete, as no important element of diagnosis appears to have been omitted. The student who wishes to acquire a knowledge of the most important points to observe in case taking will find in Dr. Duffey's suggestions a trustworthy guide, and the busy practitioner can conveniently refresh his memory upon many points, which in a rapid examination of a patient might otherwise escape attention. If Dr. Duffey should, as we hope, find it expedientt to issue a third edition, we would suggest that its value would be enchanced if it were printed in a form to admit of its insertion in the usual visiting list.

H. R. H.

The Provincial Medical Journal,

FEBRUARY, 1889.

There are few things on which the generality of people are more imperfectly informed than on those concerning the weather, and hardly any on which it is more important that medical men, at any rate, should have some correct information. Only a few hours ago we saw in what purports to be a scientific periodical that the thermometer reaches 104° F. in Canada in the shade, and falls to 12° below zero. Now 100° is a very high reading for any part of Canada. At Montreal in 1875 the maximum was 87°, and the minimum 22.1° below zero, but readings over 75° were rare, and so were those below zero. At Port Stanley the highest in the same year was 81°, and in 1876 90°, while the mercury only six times fell below zero. At Quebec a maximum of 85° was only once reached. At Sangern 86°, with a minimum of 8.1 below zero. At Toronto 88° was once reached in 1875, but this was quite exceptional, the thermometer rarely reaching 80°. A Wiltshire rector once told me that he thought nothing of a temperature of 120° in his parish, nor of zero. He might as well have said that the men of Wilts. ranged from three feet in height to ten. Few people in England know what a minimum of 10°, or a maximum of 90° really does signify. We shall endeavour to compress into as brief a space as possible some facts, which will be new to many of our readers, but on which they can implicitly rely. We have been passing since the beginning of September, 1887, through a spell of almost continuously low temperatures, with heavy rain to begin with, then a long drought, and then again abnormal rain. Into the causes of this state of things we need not enter, nor, indeed, would it be easy to frame a good explanation. What are—let us ask scientifically speaking—the characteristical features of British weather? Just these: mild, but raw, damp, foggy, stormy winters, cool summers, and an overcast sky. Ours is not, on the whole, a wet climate, so far, that is, as the amount of rain in inches goes, though parts of Cornwall, Devon, Wales, the Lake District, the Western Highlands, and the Irish Mountains have a rainfall that would not disgrace a tropical Hill Country. All parts of the British Isles have a large number of rainy days, and, still worse, as far as concerns the enjoyment of out-door life, very many threatening ones. Most parts of the kingdom have a rainfall ranging from twenty-five to thirty-five or forty inches a year, distributed pretty evenly over the twelve months, but the rain falling on any given day is usually trifling in amount. Twelve hours of steady, heavy rain roughly prepresent one inch, so that the rainfall of Bournemouth would, were it continuous and heavy, be represented by twelve days and nights; that of Lincoln by eight or nine; and that of Staffordshire by seventeen or eighteen. Of course, however, tremendous downpours, though rare, are not unknown. One inch and a half usually falls on the wettest day of the year at every meteorological station in the United Kingdom, but not a year passes on which four inches do not fall at one or more stations. But vastly larger amounts may fall—at Black Hambledon, near Todmorden on July 9th, 1870, the rainfall exceeded nine inches, and at Scarborough on August 6th, 1857, the only rain gauge in the town was found to be running over, it held nine inches and a half; probably the actual fall much exceeded that figure, and it may be assumed that even in our temperate climate nearly twelve inches of rain may fall in a day, and three inches, at long intervals, have come down in a few hours in thunderstorms. On the Khashia Hills N.E. of Calcutta, 6.10 inches of rain are considered to represent the average fall, while at Kurrachee in the same vast country the fall is only seven inches. Even in our Lake district many stations register 100 inches a year, while one reaches 140, and another 175. Were our sky clear, and had brilliant sunshine instead of our normal laden canopy, it is probable that in most parts of England we should have to complain of drought much as they do at Madrid, and that too did our rainfall not diminish. But placed as we are, full in the course of the Atlantic currents, and surrounded by water, we have a damp atmosphere, a cloudy sky, and gentle rain on one hundred and fifty days a year in the south, up to two hundred or two hundred and fifty in the west and north. No day is counted rainy on which less than the one-hundredth of an inch falls, that is a ton to the acre. There is much less difference between a dry and a wet year than commonly supposed, for the driest season may have a few very heavy rain storms, and the excess of one part of the year is commonly counterbalanced by the deficit of another season. If the normal rainfall of a district is twenty inches, a departure of five inches either way is exceptional. At the same time the rainfall is that meteorological factor which, taking the year round, has the greatest tendency to depart from the mean, and even in England we may have a whole month without rain, and next year six or eight inches in the corresponding month. A season, too, may have in one year several times as heavy a rainfall as in the corresponding one of another year, but the annual fall never departs from the average to a very great degree, and it would be startling to find the rainfall double as heavy in the wettest year as in the driest on record, although over small areas such a thing may happen.

The prevalence of bright sunlight shows very considerable departure from the mean in different months and seasons. The greatest absolute amount is in the south of England, at Hastings and the Channel Islands, and ranges from one thousand five hundred to one thousand eight hundred hours, or five hours a day, the year through: nearly two-fifths of the time the sun is above the horizon. In the midland districts the sun shines much less than at Bournemouth and Hastings, and at Buxton, which is singularly neglected by the sun, the total number of hours may fall as low as six hundred or rise to nine hundred, so that a sunless week at Buxton, even in summer, is not rare. Such an occurrence at Bournemouth is a phenomenon hardly heard of. But there is often a vast difference in the sunlight in corre-

sponding weeks of consecutive years, even in the same place, and one week may have two hours, the other sixty or more. Still, even in the matter of sunlight, the longer the time over which observations extend, the more closely does the total approximate to the normal mean. Nowhere in England or the United Kingdom do we get the magnificent weather of Spain, or Italy, or Virginia; nowhere do we have the sun glowing like a ball of fire, standing out from an unclouded sky, a veritable blazing globe, as we have seen it in November in low latitudes. Our finest summer days are always hazy, especially in dry weather, and at a little distance from the south coast, and the lights and shades are comparatively ill-defined, at the same time we could find many worse climates than ours, and a long burning spell is not an unmixed advantage to health or to the gardener.

Now let us come to the temperature. Here again we find the annual mean more constant than is usually supposed: a departure of three degrees either way is almost unheard of. What does this mean? Well, just this: the mean temperature of Bournemouth is, the year through, three degrees higher than that of Wolverhampton, so that it hardly ever happens that Wolverhampton has a year as warm as that experienced at Bournemouth; nor does a very cold year at the latter, fall to the usual mean of Wolverhampton. The mean temperature of Rome is full 12° above that of London or Bournemouth, and nearly 15° in excess of Wolverhampton. Between Scilly and London, which are often cited as showing great differences of climate, the difference of mean temperature is less than two degrees, while between the extreme south of our island and the most northernly of the Zetlands, it barely reaches six. But the January temperature of Scilly is 45°; that of London is 39°. By March London is fast overtaking the former, and when July comes the London mean is five or six higher than that of Scilly, with a far higher day reading, so that a summer day in London is a very different matter to a Scilly one, and incomparably pleasanter. Between the south of England and the Northern Isles there is little difference in January, but July has a temperature eleven degrees higher in the former than in the latter, with a still greater day inequality. We are only speaking of means or averages, and we will explain how these are roughly taken. A thermometer is placed over grass, four feet above the ground, in a Stevenson-covered screen, painted white, at some distance from walls, houses, and trees. The daily maxim and minim are accurately recorded, then added together, *one* is deducted, and the remainder is divided by two; the result is, *roughly, the mean.* An important hint ought to be given to amateur meteorologists: common bath thermometers, hung up in porches and against walls, are of no earthly use, and record, if accurate, readings many degrees too low on hot days, and several degrees too high in bright nights. Again, spirit thermometers are often found to have a little spirit condensed in the part of the tube furthest from the bulb, and consequently they sometimes give a reading 12° too low. Not only do wide differences obtain in the means of corresponding days, but there may be wider differences of another sort which we will briefly glance at. You may have a cold night and a hot day, or a warm night and a cool day. For instance: the highest and lowest readings of a London July day and night may be 76° and 44°, giving a mean, very roughly, of 59° or 59.5°, or the respective readings may be 64° and 58°. In the former case the sky has been clear, with brilliant sunshine in the day, followed by rapid radiation at night; in the latter, a wet day has accompanied a dull night. In this way it comes about that a spell of brilliant midsummer, or still more often of May weather, with high day temperatures, may actually be below the mean of the season, although people may be talking and complaining of intense heat, while at another time the mean may be much above the average, although the cool, sunless days lead people to talk of its being strangely cold.

The mean temperature of a place teaches little as to its productions, or as to the pleasantness of out-door exercise. For example, one may have a great summer heat and intense winter cold, or a great deal of fog, damp and wind, which make the summer days disagreeable and the winter ones unbearable. Most people would prefer a hot, calm summer day to the damp, musty weather of Cornwall, while a calm frost is comparably less disagreeable than the windy damp of the South West Coast, where, with the thermometer at 40°, no great coat or mackintosh will keep out the searching, raw wind. The most unpleasant June and July we ever passed were in Cornwall, near Land's End, the thermometer seldom, at mid-day, exceeded 56°, and we had mist and fog, and rain. A remarkable instance of the small value of means is afforded by the respective climates of the northern shores of the Caspian, and of the Hebrides; both have much the same mean temperature, 45° F., but on the Caspian, and near the Ural Sea, there is intense frost, lasting for some months, which is followed by a long summer of transcendent brilliancy, and burning heat; there corn grows luxuriantly, choice vines, peaches, apricots, and mulberries bear fruit abundantly, while in the Hebrides, where snow rarely lies, and thick ice is almost a phenomenon, the summer is so little better than the winter, that corn seldom ripens, and is always of inferior quality, and fruit of any description is an impossibility. Candidly speaking, therefore, the Hebridean climate, though it has the doubtful advantage of equability, and of a mild misty winter, is far less adapted to successful agriculture and out-door amusements.

Which is the most disagreeable climate, is hard to say; some people would say that of Edinburgh or Cornwall. Admiral Fitzroy gives the palm to the countries on the Straits of Magellan. "It is so disagreeable," he says, "that the country is almost uninhabitable. Clouds, wind and rain are continual in their annoyance. Perhaps there are not ten days in the year on which rain does not fall, and not thirty on which the wind does not blow strongly, yet the air is mild, and the temperature surprisingly uniform throughout the year." The temperature of that ill-omened

region is uniformly low, rarely falling below freezing point, and as seldom rising above it. Extremes of cold never occur, and even with the thermometer at freezing point the screen of vapour mitigates the rigour of the climate. In this way it comes about that the vegetable and animal life of Tierra del Fuego, and of the mainland of Western Patagonia exists under apparently anomalous conditions; vast forests adorn the mountains sides; ferns closely allied to tropical ones grows splendidly, large woody-stemmed trees of fuchsia or veronica may be seen in full flower, parrots abound, and humming birds are seen in great numbers as low as 53.5° S. latitude. The absence of frost favours many kinds of productions, while the low summer heat is equally injurious to others.

Nothing tends so greatly to make severe winter cold endurable as a perfectly calm fairly dry atmosphere, and it is not too much to say of 20° F to a well clothed person is not so disagreeable, under these circumstances, as one of 40° with a keen wind blowing and the air nearly saturated. With a practically motionless atmosphere it is possible to get warm with the thermometer at zero, or even lower. But how seldom this kind of weather occurs in these islands. Almost at any season there may be in England a difference of 42° between the mean of corresponding days in different years, though this of course is very rare. The greatest departure in the temperature of months, weeks, and days, occurs in winter, the least in summer. For example: the mean of the coldest mid-January day in London is 38°, but January 20th, 1838, had a mean of 10.7°. A mean as low as 20° is, however, very unusual. On the other hand, the hottest July day of modern times had a mean of 79.5°, say 15.5° above the mean, against a January deficit of 25°, while a July day this year had a mean of 49°; a deficit of 15° as against January 24th, 1834, with one of 52.7°, an excess of, say 17°. In London, the thermometer has very occasionally, at long intervals, fallen to zero, and even three or four degrees below, while the highest readings have been 96.6 and 96.8 in July. On the other hand, the lowest recorded reading in the south of Scotland has been twenty-two below zero, and a day in Scotland, with a mean of zero, was once recorded. Once every other year the thermometer touches 90° in London, but in the following winter the minimum may not fall below 23°, giving an annual range of 65 or 66°.

At Ashdall, Alton, Hants, a maximum reading of 101° was recorded on July 15th, 1881; this, as far as we know, is the highest reading ever recorded in England by verified thermometers properly placed. So local, however, are very high or very low readings in the United Kingdom, that in July, 1881, the maximum reading at Cockermouth only once exceeded 70°. Again, in the memorable frost of January, 1881, while the minimum fell 15°, 20°, and even 22° below zero at some places, it was as high as 24° above zero at Valencia, 26° at Guernsey, and 29° at Scilly. In selecting a place for change of air or a holiday, a most important consideration is to get abundance of moderate warmth, brilliant sunlight and rainless days. The south of England answers these requirements fairly well from the beginning of May to the close of September, but during the winter all parts of the United Kingdom are bad—the drier, colder, North Eastern districts having keen searching winds, while the South Western ones have a continuance of wet wind and raw days, with temperatures so low that out-door exercise is not pleasant except to the very robust and young.

Climate has a tendency to arrange itself under one of two types—the continental and the insular—that is into large diurnal and seasonal ranges from, say 30° below to 110° above zero, a not uncommon range in many parts of the Northern states of the American Union and small annual and seasonal range like that of Scilly, from a minimum of 30° to a maximum of 70°. The most remarkable instances of the two types would be found on the one hand in Northern Siberia, and on the other in some small equatorial island. The nearer the equator, from the small difference in the length of the day, and the little change in the angle with which the sun's rays strike the ground, the greater the equability of thermometer all the year round. So that in extreme cases the annual range, night and day, may only be from a minimum of 80° to a maximum of 90°. But between the extremes of both types of climates there are countless varieties, and one can only roughly say that the nearer the sea and the shorter the distance from the equator the less the annual and the diurnal range, while the further from the equator and from the sea the greater the extremes.

Hardly a year passes that some wiseacre does not write to the papers that the thermometer in his garden has reached a higher point than at Calcutta, or in Jamaica, or that the lowest reading has actually been higher than at Athens or Palermo during the same season. Both statements may be rigidly true, but the inference from them that the climate of England has anything in common with a tropical or sub-tropical one would not follow. It is quite possible that on some abnormally hot day, just for three or four hours, the thermometer may read as high in Hants. or Sussex as at Calcutta, or some other damp place not far from the sea in or near the tropics; but whereas in England the thermometer only stands at that high figure for a few hours, once or twice in a couple of years, in the tropical town it will read as high for six, or eight, or ten hours a day for weeks, and even months at a time. The absolute highest readings, however, are not usually on the equator, but 15, 30, or 35 degrees north or south in dry regions like the plains of India, or the oases of the Sahara or the dry plains of Australia, and there the daily maxim may reach 100° to 110° for a long time, occasionally running up to 118° or 120°, or even at rare intervals to 127°, or even 132° or 133°, the last the highest recorded maximum ever known. By the way, as reliable meteorological stations are infrequent in tropical lands, especially in the great rainless tracts, we do not know with absolute certainty what figure might be reached in some exceptional season, possibly 140° or 150° as an extreme. Against this, however, may be set the fact that the extreme

readings of 127° to 132° have not been surpassed during the past forty or fifty years, although the hottest regions of the earth have been repeatedly traversed by explorers well armed with instruments, and knowing thoroughly how to place them.

Everyone must have noticed the great charm of a bright, sunny, calm day, although the temperature may be quite moderate, while nothing is more depressing than a day on which, without sharp, actual cold, the earth and sky are enveloped in a dull uniform gloom. A traveller in the temperate but highly favoured parts of the world, like Florence or Malaga, is greatly surprised at the crowds whom he sees in the open air on fine evenings and cool days compared with the small numbers to be seen in England at the same season and hour. Had we the sunlight and genial atmosphere of southern France how quickly would our habits change: our houses would be thrown open, we should sit out in our gardens, perhaps in the streets, and no longer take "our pleasures sadly." All we need is a calm dry atmosphere for perfect enjoyment, not necessarily a high reading, and in parts of Colorado people are said to sit at open windows without extra clothing with the thermometer at 31°, and not to complain of cold.

We have received from the Society for the Prevention of Cruelty to Children a pamphlet entitled, "The Child of the English Savage," written by Cardinal Manning and Benjamin Waugh, exposing the cruelties practised on helpless children by men—or rather, brutes—with ungovernable passions, and calling for the helpful aid of the people of England to protect innocent children from such cruelties. To the public, the revelations made by the Secretary to the Society must be startling, but to medical men in public positions the facts will not be surprising. As a profession, we have for years and years, through our professional journals, asked for legislation which would protect infant life. We have again and again called attention to the methods by which in this country infanticide was encouraged and allowed. Baby-farming has been fully exposed in the medical press; the insurance of infant life has been denounced; the ill-feeding of infants has been exposed, and remedies suggested; the various social aspects of these evils and questions have been pointed out in the columns of the medical journals.

It takes time to waken up public opinion; and, probably as the result in a certain measure of what the medical press has done in the past, we have at the present moment a powerful organisation, with admirable machinery, ready to do battle in the cause of the unprotected. The indictment brought in this pamphlet against the English savage is a heavy one, and unfortunately, but too true. We heard the Rev. Benjamin Waugh, at a recent meeting for the establishment of a branch of the Society in Halifax, give additional facts substantiating those already published in his pamphlet, and showing how widespread were the evils therein complained of, and how necessary it was that parents should be taught that there was a supervision over them, and that children could not be treated with impunity. The great difficulty a society has to contend with arises from concealment and from ignorance. Infanticide has been very ably treated of in this journal by Dr. Francis Vacher, of Birkenhead. Its causes are but too well known. The legislature must in due time consider the subject. Awaiting that consummation, the assistance of the medical profession is invoked by the London Society for the Prevention of Cruelty to Children. Medical men can assist very materially by sending to the Secretary well-substantiated facts, showing especially how far cruelty has been practised, in what manner, giving details of death which have occurred with or without medical treatment, and whether insurances existed on the lives of any children which have died. The greatest difficulty in connection with the subject is, how to reach the children of a floating population—as, for instance, the tramps who go from town to town, and next, the children born out of wedlock. The insurance of infants and children has been unfortunately made a bad use of; and admirable though the principle is, owing to this abuse, some legislation is earnestly required. It seems a terrible thing to think that a child's life should be taken away for the sake of £3 or £4; but that is the extreme way of putting it. It is not that the child is deliberately killed: there is indifference and neglect, and the child is allowed to die. If the child be ill, medical advice is only sought *in extremis*. In infanticide as practised, infants and children die a slow, lingering death. The law cannot touch the parents who offend in this way. The greatest kindness such parents could do to their children would be to cut their throats, and put an end to their misery at once; but here the law would at once step in, and the savage would swing at the end of a rope, with his head in a noose, a process which the savage does not like. The crime is one of omission, not of commission. Much helpful work may be done in all our large towns by well-organised committees attached to the parent Society in London—work not alone of a penal nature, as in the exposure and punishment of cruelty to children, but in reformatory and educational work. For instance, who is really responsible for the slaughter of the innocents in the case of unmarried women? They are confined in our workhouses, and when discharged at the end of a month may go out into the world more helpless than when they entered, because they have an additional burden to bear, and another mouth has to be fed. The woman is weighted down and disgraced. She has to begin the battle of life again, but against unequal odds. Her infant is a standing testimony against her, and it must be hidden away, else she cannot obtain food for either it or herself. It is very effectively disposed of, though it is not deliberately killed: it is put out to nurse. What agency does there exist to prevent the unfortunate woman from sinking and being engulphed? Fortunately, we do find a few devoted women who are willing to take upon their own shoulders the burden of their sisters' shame, who enter our workhouses to find out how they can help, and who do not

disdain to lift up fallen women, thereby giving the lie to Byron's satire—

"That every woe a tear can claim,
Except an erring sister's shame."

But individual effort cannot supply the want of organisation, and herein lies the value of such a society as the one under consideration. We must recognise the existence of these unfortunates, and this is a first step towards helping them. It is women's work to do so, and it can be better done by means of a committee than by individual aid. Next in importance to the protection of illegitimate children comes the education of mothers as to the proper method of feeding infants, so that the scope of work is a very wide one. The help of the medical profession is essential in all this reformatory work, and we believe we are warranted in saying that it will be readily forthcoming.

Milk is such an important article of diet, so largely used—in fact, indispensable—that we must welcome any reforms which tend to give us this model food free from contamination, and free from disease. The sanitary condition of dairy farms generally is most lamentable, though in many cases it is true that great cleanliness is observed in the dairy, and that vessels are scalded and washed, and the milk is placed in a clean receptacle, but even in the cleanest dairies the atmosphere may be polluted, owing to deficient drainage and close proximity to the other premises in which the cows are laired. The condition of the cows at the time of milking has not received much attention, the milk being sieved subsequent to the process, so as to strain solid particles, hair, etc. There is, we believe, incontrovertible evidence to prove that serious epidemics have arisen from infected milk. But though in some cases reported, it must be admitted that the evidence is of a weak nature, and the milk has been wrongly incriminated. This does not, however, detract from the necessity of making provision for the proper lighting, ventilation, water supply, and drainage of the dairy and cow-shed. In an excellent article read before the Epidemiological Society of London December 14th, 1888, Mr. Shirly Murphy reviewed our present position as regards legislative interference with milk-selling, and sketched an outline of the additional legislation required for the protection of the milk against infection or contamination. Sanitary reformers are too often accused of being crotchety, impracticable, and of not sufficiently considering expenditure; but we think it will be seen that the provisions desired by Mr. Murphy are calculated to benefit the farmer, because under proper sanitary conditions the cow will become more valuable as a producer, and its health will be better maintained. The cow has, indeed, been treated with too little respect; she is exposed in the summer time, and then is transferred from fresh air into a close, confined, dark shed, to conditions which are in many instances lamentable, and here she is expected to give milk of good quality.

In sanitary administration we have first, then, to deal with the cow and her shed, and in this connection will have to be considered cubic space necessary for each cow, ventilation and drainage, and especially of water supply. Mr. Murphy's recommendations on this point are not excessive.

Secondly, we have to deal with milk when it has left the shed, and is carried to the dairy. Rules of cleanliness cannot be too rigidly carried out, and we certainly cannot see that the farmer can object to conditions which will increase the value of his products.

Thirdly, when the milk has left the farm it passes into the hands of distributors of all kinds. Milk-shops of late years have very much improved, and they will still more improve if customers themselves would take a little more interest in the subject. Legislation is here required, however, for the benefit of that large class who cannot afford to be too particular as to the class of shop they buy their milk from.

Of course, many who are interested in the milk traffic will resist all interference with what they consider their rights. They consider that legislation interferes with their trade, and they imagine that they should be allowed to conduct it in their own way and under any conditions. This is a delusion. Every individual has a right to conduct his trade in his own way, but it must not interfere with the greater right of his neighbours and fellows. This is the principle which underlies all legislation and control of workshops, factories, hours of labour, employment of children, etc. In London, private initiative has so far forestalled State interference that we have model dairy farms, model shops, and model distribution of milk, all undertaken in the interests of the consumer. No loss has been experienced by the company which have thus wisely set their houses in order, and their action should stimulate those in the trade to imitation. Mr. Murphy's paper is a valuable contribution to the subject, and must be the means of reform.

The hypodermic method of treating syphilis has, during last years, grown in popularity abroad. Its history since 1885 is very ably given in an article in the *Progrès Medical*, January 5th. It deals with the subcutaneous injection of calomel. The following abstract may be of some interest to those who have tried the method, whilst it may induce others to put it to the test.

1. *Injections of Metallic Mercury.*—This kind of injection has been performed either with liquid mercury or with mercury dissolved in either fat or oil. The first mode has been performed by Lutaud and by Procharow. These authors inject one gramme of the metal in the subcutaneous tissue. Procharow adds some water, and then manipulates the injection. Specific complications disappear in from three to six weeks, without exciting disturbance of the digestive functions. The injections may be repeated three or four times a week, using 0 gr. 50 c. of mercury

each time. Lang mixes the mercury with oil, to which may be added a little phenic acid to prevent fermentation. Each cubic centimètre contains 0.23 centigrammes of mercury. He performs two injections a week in the dorsal region, recommending, in specific ganglionic affections, that they should be made in the track of the lymphatics.

2. *Injections of Calomel.*—The first injections were made by Scarenzio and Smirnoff, who have since developed the method. They have since been tried by Ambrosoli, Sigmund, Gallien, Balzer, Walraszewski, Kapp, Chalzen, Neisser, Stonkowenkow, Kreche, and Bloom. Calomel is dissolved in solution of glycerine, mucilage, oil of vaseline, or chloride of sodium. The favourite seat of injection is the region of the buttocks, the part being manipulated so as to diffuse the liquid, though some authors condemn this as tending to favour abscess. The injections should be performed with antiseptic precautions. The needle should not be withdrawn until all the liquid has been absorbed in the subcutaneous tissue. At the first time, an injection of 0.10 c. is made, the operation being repeated in fifteen days. Two *séances* are generally sufficient in mild cases, but in rebellious cases it would be necessary to use the injections four or six times. The injection produces little or no pain at the time, but usually in three or four days the region becomes sensitive, and sometimes an abscess forms at the seat of the puncture; sometimes, in place of the abscess, nodosities are produced, which are more or less painful, and last ten or twelve days. In employing it M. Balzer has never observed the formation of abscess. In some individuals stomatitis is produced. The object proposed is to obtain a slow absorption of mercury without submitting the patient to repeated medications. In effect, on examining the urine mercury may be found from sixteen to twenty-four hours after the first injection, and even so long as the fifteenth day, though most of it is eliminated between the third and fifth day. Secondaries disappear in from two to four weeks, but tertiaries are more rebellious.

3. *Oxides of Mercury.*—Thadeck and Walraszewski have employed the yellow oxide of mercury. It is mixed with mucilage of gum arabic or oil of vaseline in proportion of 1 in 30; each injection contains 0 0.4 c. of the active substance. Three to five injections are sufficient. Recent preparations should be used, as the oxides decompose easily. The operation causes a little pain, which ceases in from twenty to thirty hours. The region should not be beaten; the patient should rest. Abscess and nodosities are rarely observed.

4. *Phenite of Mercury.*—Gamberin first used this salt, Shadek and Irostygin giving it by injections, made by mixing. The injections are not painful. Ten injections are sufficient.

5. *Salicylate of Mercury.*—This has been employed by Sylva, Arango, Moura Brasil, and Neves de Rocha, who used a solution of 00.5 milligrammes.

6. *Formamide of Mercury.*—This was first used by Liebreich, then by Zeissel and Koppe. The pain of the puncture lasts about twenty-four hours. Relapses are frequent after its use.

7. *Succinimide of Mercury.*—This has been employed by Wolfe in a two-per-cent. solution. Two grammes of this salt contain one gramme of mercury. He performs, each day, an injection of 0.02 centigramme. The puncture is painful.

Peptonate of mercury has been employed by Martineau, and Bochart has employed the bichlorate of mercury with serum, adding thereto the chloride of sodium. Mandelbaum has employed bicyanide of mercury in a one-per-cent. solution, adding 5 per cent. of cocaine to relieve pain. The addition of cocaine seems desirable, and some antiseptic will also prove useful.

Which treatment should be preferred, internal, inunction, or hypodermic injections? It all depends on the patient. For a patient whose digestion is normal, and who can give time to treatment, the internal seems preferable, especially in presence of the inflammatory phenomena produced by the injections. In the class of patients met with at the cliniques the injections are indicated. In grave affections where it is necessary to apply immediate remedy inunction is more rapid. What sort of injection should be preferred? In indurable affections, where incessant action of mercury is preferred, calomel, the oxide of metallic mercury in the form of *huile grise* should be utilized. In slight cases, in which patients cannot support the action of mercury by the digestive tract, the soluble salts should be employed.

Annotations.

"Forsan et hæc olim meminisse juvabit."

SIGNS OF THE TIMES.

In looking over the daily journals, we are pleased to see such headings as "Medical prosecution for irregular practice." Lately, we have had a fair number of these paragraphs, so that they present us with signs that the unlicensed practitioner is not likely to have altogether a good time. At Hoyland, W. Barnsley, a man who had been practising there for nearly ten years, was find £17 10 with the option of two months imprisonment. We want some more such lessons from the Bench.

EUTHANASIA.

Some medical experts have been investigating the best methods of producing death, and they have found that euthanasia may be most quickly promoted by means of electricity. This agent produces death painlessly, we presume, and instantaneously. It is very considerate to take such measures for the benefit of our criminals, though we have no doubt that they fail to appreciate the efforts of those philanthropists who propose to substitute electricity for hanging.

THE ABORTIONIST IN CHICAGO.

The *Journal of the American Medical Association* is to be congratulated on the bold manner in which it has spoken out on the subject of professional abortionists. The profession in America have been silent in this respect. Now that the national journal of America has had the courage to break the silence, we may expect a crusade against the men who disgrace the profession in the States. The occasion which induced the journal to tackle the subject arose through the action of the *Chicago Times*. That paper had the daring to print "the names of midwives and physicians who declare that they are ready to do murder, and most foul murder, for money." Well may the journal say: "Criminal abortion, the national disgrace, has culminated in the exposure in Chicago. It is to be regretted that the matter was not worked up at the same time in other cities, so as to clear the country of the harpies that foul the medical profession." Now is the time to clean the Augean stable.

ROUTINE ANÆSTHETICISM.

Familiarity, it may be truly said, begets contempt. Men accustomed to firearms are too frequently very careless. Witness the numerous accidents reported as occurring through the carelessness of leaving guns about with the charges undrawn. The profession has ever been alive to the dangers of chloroform; but we regret to say too great familiarity with this boon has led to a disregard of the possible contingencies that may happen. Chloroform is given too rapidly, it is not even measured, and as a consequence we have but too many deaths. Professional anæsthetizers are not very numerous, being only to be found in the largest cities. Chloroform has to be very frequently given by one practitioner for another in an emergency, so that we cannot too strongly impress upon practitioners the importance of what they undertake in giving chloroform.

MEDICAL AID SOCIETIES.

We have not heard recently of the London Medical Provident Society. Is there reason to hope that the scheme is likely to end in failure, and that the vigorous and widespread opposition on the part of the general practitioners to it has had some effect? We regret to find that private medical aid societies, with all the paraphernalia in the shape of handbills, posters, painted windows, and screens, are still in full vigour. The College of Surgeons and Physicians are fully alive to a sense of their dignity, as we have seen in regard to their action relating to Sir Morell Mackenzie. His printed matter offended their sense of propriety. Could not the Colleges look at the printed matter circulated by members in the lower walks of the profession? More harm is done to professional interests and respectability by the latter than the former. Sir Morell Mackenzie, of course, is in the highest rank; hence the kind attention he has received from his Colleges.

THE IRISH MEDICAL SCHOOLS AND GRADUATES' ASSOCIATION.

A most successful conversazione in connection with the above association was held on January 15th, in the rooms of the Medical Society of London. The guests, to the number of 300 ladies and gentlemen, were received by the president-elect, Dr. R. Fegan, in the unavoidable absence of the president, Dr. Macalister, F.R.S. Among those present were Lord Ronald Gower, Sir William M'Cormac, Director-General Dick, C.B., R.N., Dr. Robert McDonnell, F.R.S. (Dublin); Dr. Ericksen, F.R.S.; Dr. Macnaughton Jones, the President of the Harveian Society (Mr. Sedgwick), Surgeon-General Manfold, Dr. Robert Barnes, Dr. Norman Kerr, Deputy-Inspector-General Mac Clinton, R.N.; Dr. Crowe (Worcester), Dr. Gilbert Smith, Dr. Mapother, Mr. Bruce Joy, Lieut. G. Dick, R.E.; Mr. George Cowell, Dr. A. E. Sansom, Mr. Wallace, J.P.; Surgeons-Major Rabully, Bartley, Roe, and Marturin. The hon. secretaries, Drs. J. Stewart (Clifton), and P. S. Abraham. Provisions were made for all varieties of tastes, the music being exceptionally good. It consisted mostly of Irish melodies, or part songs from the collection of the Dublin Strollers, rendered by Miss Rose Hervey, Mr. O'Shaughnessy, Miss Aungier, Mr. R. Groome, Mr. L. Clive, and several well-known amateurs. Recitations were also given by Mr. W. H. Stephens and Miss Elaine Verner. Some good specimens of instantaneous photography were exhibited by Messrs. Robinson & Sons (Dublin and London). There were many other exhibits, including a portable telephone by Mr. W. C. Greenhill; microscopes, ophthalmological, and other instruments by various well known firms. Irish artists were also well represented by Mr. Bruce Joy's sculpture, and portraits from the easel of Mr. Thaddeus. The walls were also adorned by specimens of the work of Miss Inglis and Mr. Mac Cullum—old engravings, etc. Altogether we must sincerely congratulate the Irish Graduates on this successful gathering, which is the last of the series of meetings by which they have been celebrating the conclusion of the first decade of their existence as an association.

INFANTILE MORTALITY FROM SYPHILIS.

At the meeting of the Obstetrical and Gynæcological Society of Paris, December, 1888, Dr. L. Le Pileur read a valuable paper on "Infantile Mortality caused by Syphilis," founded on documents collected at the prison of St. Lazare. There has been much diversity of opinion as to the number who die annually from syphilis in England and other countries. There is too much conjecture to attach any importance to the numbers given. It is difficult to collect accurate statistics in a case of this kind, and we therefore welcome Dr. Le Pileur's contribution, as he was able to give information derived from a small centre, where the conditions of correct observation could be fulfilled. The paper is of moderate length, and will be found interesting to those who require information on a very important subject.

BRITISH GYNÆCOLOGICAL SOCIETY.

At the annual general meeting of this society, held Wednesday, January 9th, 1889, the following gentlemen were elected officers and council for the year 1889: *Hon. President:* Robert Barnes, M.D., F.R.C.P. *President:* Arthur Vernon Macvan, M.B., B.A., F.K.Q.C.P.I. *Vice-Presidents:* Fancourt Barnes, M.D.; J. G. Sinclair Coghill, M.D.; J. Halliday Croom, M.D.; Thomas M. Dolan, M.D.; William Gardner, M.D.; W. Chapman Grigg, M.D.; William T. Lusk, M.D.: James A. Mansell-Moullin, M.B.; Thomas Savage, M.D.; W. Japp Sinclair, M.D.; Brice Smyth, M.D.; William Walter, M.D. *Treasurer:* George Granville Bantock, M.D., F.R.C.S. Ed. *Librarian:* Bedford Fenwick, M.D. *Council:* William Alexander, M.D.; Thomas M. Cambridge, M.R.C.S.; William A. Dingle, M.R.C.S.; R. W. Edginton, M.D.; Arthur W. Edis, M.D., F.R.C.P.; George Elder, M.D.; C. Egerton Fitzgerald, M.D.; Robert Harvey, M.D.; A. Philip Hills, M.R.C.S.; Francis Imlach, M.D.; John A. Lycett, M.D.; Thomas Morton, M.D.; James Murphy, M.D.; F. Albert Purcell, M.D.; J. A. Rawlings, M.R.C.P.; W. Reid, M.D.; C. H. F. Routh, M.D.; Samuel Sloan, M.D.; J. Grey Smith, M.D.; Heywood Smith, M.D.; W. J. Smyly, M.D.; W. Dunnett Spanton, F.R.C.S. Ed.; Lawson Tait, F.R.C.S.; Edward G. Whittle, M.D. *Hon. Secretaries:* Bedford Fenwick, M.D.; Richard T. Smith, M.D.

THE LENDING OF PRESCRIPTIONS.

This practice is becoming too common, one prescription being made to do duty almost for a whole village. Some one consults a physician for rheumatism, the prescription does good, it is copied and may be sent all over England; for if the original holder of it happens to have a friend suffering from rheumatism, it is at once assumed that the prescription which did so much good in one case will do so in another, so the prescription is at once sent off. This is not the only grievance. The patient takes the prescription to the chemist, and gets it made up as often as she likes, perhaps taking a medicine which is highly injurious too often repeated. We believe this to be a real grievance. Some remedy is required. We should be content with the German system, where a prescription cannot be refilled without the signature of the prescriber.

HACKNEY CARRIAGES AND POISONING.

The "Mystery of a Hansom Cab" becomes explainable when we find out in the course of the story that a poison has been administered. It would appear from *Le Progrès Médical* that we may have poisoning from the very anxiety of the *cocher* for the comfort of his passengers. M. Gautier has had to direct the attention of the Prefect of Police to the dangers of riding in hackney carriages, heated after the method—so common in Paris—of Chaufferettes. During winter, many of the cabs are thus warmed, and when the windows are closed, owing to the evolution of oxide of carbon, the voyager may find himself overpowered by the fumes, and symptoms of poisoning may take place. Even some of the distinguished members of the Academy of Medicine have thus suffered. There is greater danger when a number of persons occupy a carriage. A coachman named Jean Hiver was poisoned in his own cab. Some other system of heating will, no doubt, now be adopted.

TOBACCO.

We have continual scares about the evils of smoking. We believe a good deal of the abuse to which tobacco has been subjected has been produced by excess, and by disregard of what we may call ordinary hygienic rules. For instance, men will persist in using pipes which are too old; they will not clean out the pipe before refilling it; and we frequently find that this neglect is at the bottom of the many troubles from which smokers suffer. The smoker's heart and the smoker's pulse are not very commonly found, save in those who smoke to excess. The moderate use of tobacco is, as a general rule, harmless. But here we should say that good tobacco should be obtained.

THE INCREASE OF CANCER.

Sir Spencer Well's Morton lecture has frightened a number of people, and for some time to come we shall hear a good deal about cancerous diseases. It was made a subject of question in the House of Commons. When General Grant died in the United States, there was a large number of papers published upon cancer, and here in England we may thank the late Emperor Frederick for stirring up scientific zeal. The evidence at present offered us cannot be contradicted, and it is unfortunately but too true that cancer is on the increase. The profession is now forearmed, and hoping that investigation will follow on our knowledge, we may be able to do something to prevent the disease spreading further during the next decade.

HYSTERORRHAPHY.

Under this name we have a new operation for displacements of the uterus. It comes to us from America, and is thus introduced to us by the *New York Medical Record:* "The cervix uteri having been subjected to an incalculable amount of more or less harmless stitching, both by the experts and those willing to become so, it is now proposed to devote a stitch or two to the hitherto strangely neglected fundus uteri. We may as well confess *à priori* our feeling in favour of hysterorrhaphy, as Dr. Howard A. Kelly, of Philadelphia, has called this new operation, with which his name has become justly and prominently associated. The fame of this gynæcologist has too long grown, *pari passu*, with the number of his cervical stitches. It is time that the trachelorraphist should be told that the cervix is not the universe, even in a strictly uterine sense. He should learn that there may be complete cervical happiness, although the fundus still weeps away down in the hollow of the sacrum, on account of a prior attachment. The hysterorraphist is, of all

persons, the one best qualified to restore the just equipoise of things uterine by placing his beneficent stitches where they really belong, and no longer truckling to that arrogant gynecic monopolist, the cervix uteri, in spite of all its amiable accessibility. Of course, sewing the fundus is an innovation of a somewhat revolutionary kind. If there needs must follow division in the serried ranks of the conquering hystero-stitchologists, let the new party lines be drawn on this local issue of cervix or fundus. For that both parties will continue to stitch to the end of all time, nobody can reasonably doubt. Seriously speaking, however, the new operation of attaching the uterus to the abdominal parietes is a rational procedure in otherwise unmanageable cases of displacement. The operation itself is neither very difficult nor specially dangerous. It extends a just hope of relief to those whose sufferings are not likely to be over-estimated.

THE HOG AHEAD.

Under this heading the *New York Medical Record* tells us "that the United States Government has paid more money for the investigation of the diseases of hog than it has for all the diseases of the human race." The hog is ahead, *because* the hog represents money, and we regret to say that the same remarks might be applied to other countries than the U.S.A. The public set more value on their property than they do on their own lives. If some money interest be at stake, what precautions are taken to protect it. The best legal advice is sought, counsels' opinions taken, and large fees are paid, enough to cover medical attendance for some years. But when grave illness is experienced, a few guineas are begrudged for the best advice; some even prefer to die cheaply under the 6d. doctor or the chemist. They need not grumble if the State follows them in their estimation of what is valuable.

A CAUTION FOR INSURANCE COMPANIES.

Very recently, Mr. Robottom, the Borough Coroner of Wigan, held an inquest on a woman who died suddenly in the tap room of a public-house. It transpired at the inquest that she was numerously and heavily insured, that within the last twelve months she had been insured by a person who had no insurable interest. A *post-mortem* examination was made by Drs. W. Mitchell Rorcroft and R. Prosser White, and they found chronic bronchitis of long standing, valvular disease of the heart and kidney mischief, and also were of opinion that she was sixty years of age, although she had joined the insurance company as forty-eight years of age. Death from natural causes was the verdict of the jury, and the day following the inquest, *five* applications for copies of the register were made for insurance claims. Speculative insurances are largely made in Wigan, and seem even to be connived at by the agents. Moreover, individuals other than the person insured are believed to be presented for examination by the companies' surgeons. Many of the insurance companies require no medical examination for amounts under £20 or £25, and numerous policies are issued from different offices; but even in the same office it is no uncommon thing for two or three, or even more, policies to be issued. Surely the legislature ought to step in and prevent such traffic, especially after the experience of the Liverpool cases. The Coroner of Wigan, however, is deserving of great commendation for having by means of his enquiry brought such facts to light.

A SINGULAR CASE.

A singular case has lately come under the notice of the French tribunals. A French sage femme was asked to attend a young girl (unmarried) by her uncle, who promised that he would pay all expenses if she consented, and the accouchment came off. In due time the young lady went back to her home, and was as far as the world knew a virgin. The child was put by the sage femme out to nurse, and for a time all was satisfactory. The uncle paid according to agreement, but unfortunately for the midwife he died. There had been no written agreement; both the mother and the family repudiated all liability for the child, and preserved a decorous silence when written to. Ultimately the sage femme getting no redress entered the case into court, with the result that she lost her case, and is now actually expected to bring the child up until it has reached its majority.

MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY.

The report of the above society was presented at the quarterly meeting of the committee, held on January 16th, Mr. Ernest Hart in the chair. The report showed an addition of thirty-four new members during the quarter, showing a total effective membership of 932. The practical work of the Sick Fund showed a receipt from previous income for the half-year of £2,610 and £183 interest, as compared with £2,288 and £53 interest in the same period of the previous year. The Annuity Fund shows an increase of £1,256 for the half-year, against £1,127 in the corresponding period of the previous year. In the Insurance Fund the income had increased, and there had been no claims from death. The income due to the Management Fund had been £518, of which only £227 had been expended. There is an accumulated saving in this fund of £2,287, which is put to the credit of the Members' Fund. The Government Returns under the Friendly Societies Act have been completed, and will be sent in during the week. The total increase in the society's funds during 1888 is £7,897 10*s*. The total worth of the society is now £28,719 2*s*. 1*d*., of which £743 3*s*. 1*d*. is with the bankers on current account, the remainder being invested in the name of the trustees (Sir Spencer Wells, Dr. W. Ord, Mr. Ernest Hart, and Mr. J. R. Lupton) in first-class securities at an average rate of $3\frac{3}{4}$ per cent. interest. The prosperous result of the year's operations has been verified by the auditors, and it discloses sound progress, economical

administration, and the most solid financial security for the beneficial extension of the operations of the society, in affording the means of provision to all members of the profession against losses, accident, illness, and the diminished earning power of old age. All documents, tables, etc., may be obtained from the Secretary, Mr. Radley, 26, Wynn-road, Brixton, S,W.

New Remedies.

Condurango Bark.—Although this bark has not received so much attention in this country as in Germany, it is evident that it possesses powerful medicinal properties, since a glucoside has been extracted from it, which has been shown, in some preliminary experiments made by Professor Kobert, to be a powerful poison. It is called *condurangin*, and is a yellowish powder, soluble in alcohol, and having a bitterish aromatic taste. The variety of condurango bark, from which it was obtained, is *Gonolobus Condurango*, Triana.

Creatine is stated by Professor Kobert to possess certain advantages over Liebig's extract, in not containing gelatinous substances, which in certain affections of the stomach prove injurious. He holds the opinion that creatine, given in doses of 0.1 gram four or six times daily, would be of therapeutic value for stimulating muscular action in cases of debility, and also in weakness of the heart and chronic debility of the digestive organs. It should be given in the form of dry powder, laid upon the tongue, and washed down with a draught of water.

β-naphthol is reported to have proved a safe and efficient remedy in seven cases of enteric fever treated by Dr. J. Mitchell Clarke, of the Bristol General Hospital. It was found to produce an effective internal antisepsis, and to lessen the duration of the disease. The intensity of the symptoms was diminished, and the tendency to boils and abscesses lessened. On the other hand, however, it was found to have some disadvantages, being liable to produce gastric disturbance, and in two cases it failed to prevent a relapse.

Camphoric acid has recently been recommended by Professor Reichert in various inflammatory diseases of the mucous membrane, especially of the respiratory passages. It is obtainable in the form of white crystalline needles, having an acid taste, is readily soluble in alcohol, also in ether, and in fixed oils to a limited extent (2 per cent.), but is soluble with difficulty in water; hence it is best to add about 11 per cent. of alcohol to the water used for dissolving it. When applied to the mucous membrane it appears to quickly exert an astringent action, and promotes granulation without causing irritation, whilst it also acts as an antiseptic. Externally, solutions containing from ½ to 6 per cent. of the acid can be used; internally, however, a ¼ to 2 per cent. solution is found sufficient. In acute angina, the use of ½ to 1 per cent. solution every three hours has been employed; in pharyngo-laryngitis and tracheitis it has been applied in the form of a spray, of a ¼ to 1 per cent. solution. In acute catarrh, wadding saturated with a 2 per cent. solution is placed in the nostrils; and in acute bronchitis, a 1 to 2 per cent. solution is used as a spray.

Phenacetin has been found to be soluble in lactic acid at a temperature of 33° C., and it has been suggested by Messrs. Mirrachi and Raffi that this fact accounts for its rapid absorption when administered, since lactic acid is usually present in the stomach. If this be the case it would appear probable, therefore, that in those cases in which phenacetin fails to give relief in neuralgia and headache, the failure may be due to the absence of that acid from the stomach, and that the addition of a little lactic acid would probably overcome the difficulty.

Thiol.—Under this name an artificially prepared representative of the natural ichthyol has been introduced, for use in the treatment of skin diseases. It is prepared from the gas-oil obtained in the distillation of brown coal by heating it with 10 to 15 per cent. of sulphur at a temperature of 215° C. The thio-sulphonic acid formed in this process is separated from the undecomposed oil, and forms a dark-brown resinous mass, readily soluble in water, from which it is reprecipitated by mineral acids or salts. It is soluble in alcohol or ether, or a mixture of the two. By neutralising the aqueous solution with ammonia or soda, the salts of thio-sulphonic acid are obtained, which are said to correspond to the natural combinations found in ichthyol.

Sulphonal, which forms the subject of a lengthy paper in the *Dublin Medical Journal*, seems to have proved, in the hands of M. Conolly Norman, to possess valuable properties as a soporific. Out of twenty-two cases in which the drug was tried, bad results were noticed only in two, and in these other sedatives had previously failed. No gastric or intestinal trouble was observed; the appetite improved under its use; the tendency to self-abuse and erotic excitement, in several cases of melancholic-mania from masturbation, was diminished in a marked manner; the sleep produced by it was natural, refreshing, and dreamless; and the patients raised no objection to taking it. Mr. Norman, while acknowledging that sulphonal may, like other potent drugs, have its peculiar dangers in certain cases, yet considers that it is, as a rule, free from danger, and is followed by trifling, if any, unpleasant after-effects.

Sparteine.—The experiments of Levascheff and Pawinski show that the use of sparteine is indicated in recent cardiac affections where compensation is but little disturbed, and the degeneration of the cardiac muscles has not progressed far; but that in advanced cases, and where œdema is excessive, it is without effect. Its action, however, is rapid, the therapeutic effects being produced in fifteen minutes. In some cases it is liable to produce irritation of the mucous membrane of the intestine. The cases in which it seems likely to be especially useful, according to Pawinski, are in nervous troubles where the heart is affected, in the early symptoms of Graves' disease, in painful sensations in valvular disease, and in asthmatic attacks in patients who have a bronchitic or emphysematous tendency.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. Kesteven, M.D.

A Pasteur Institute at Brazil (*L'Union Médicale*, December 6th, 1888).—At the sitting of the Academy of Sciences, Paris, November 6th, M. Pasteur stated that at the request of the Emperor of Brazil he had established laboratories, etc., for the treatment of hydrophobia. From February 9th to October 8th, 1888, 149 persons presented themselves for treatment. Of these 69 only were detained, the evidence of rabies being deficient in the other cases. Of the 69 cases, one died, not having been placed under inoculation until twenty-four days after the infliction of the bite. It would seem, therefore, that no ill-effects attended the measures adopted in the remaining sixty-eight cases. The actual results are not stated.

Treatment of Gôitre by Intra-Parenchymatous Injections of Iodoform Ether (*Le Progrès Médical*, December 1st, 1888).—The patient, æt. seventeen years, came under the care of Dr. Ferrier at the hospital, Bichat, on the 16th February, 1888. At the age of fourteen he first perceived the enlargement of his neck. The gôitre consisted of three tumours connected with one another. The largest tumour, on the right, was the size of a hen's egg, and was free from nodosities; the smallest, situated on the front of the trachea, was as large only as a nut. The third, situated on the left side, was of a size intermediate between the other two. The tumours were all hard and movable. Injections of iodoform ether were commenced on the February 19th; one injection daily was performed until the 10th of March (twenty-one injections), on which day he left the hospital. The injections had been practised alternately, right and left. The repetition was gradually reduced until, in November, they were repeated only once a week. There remained then only a nodule of about the size of a small nut.

Prevention of Rabies in Bavaria (*L'Union Médicale*, December 6th, 1888).—From the year 1863 to 1876 the average number of deaths from hydrophobia was stated to be fourteen annually; sometimes the number rose to twenty-three, and in one year to thirty-one. The law

having been strictly enforced with regard to stray dogs during the last seven years, three deaths only have been reported during that period! The population of Bavaria is stated at five and a half millions.

Thiol (*Der Forsschritt*, December 5th, 1888).—This substance is, according to Dr. Keeps, identical in chemical properties with ichthyol, but obtained by a different process from coal-tar. It has the synonym of "German ichthyol."

Two Cases of Cysticercus Cellulosæ in the Brain (*Forschritte der Médicin*, December 1st, 1888).—The first cases related by Dr. Bollinger was that of an individual, forty-one years of age, suffering under tubercular disease of the lungs, but who had not shown signs of brain disease. A cysticercus was found imbedded in the white substance of the right hemisphere, accompanied by chronic fibrous, and acute hæmorrhagic inflammation. The parasite had attained the size of a cherry stone, and was situated on the margin of the middle and lower convolutions. In the second case vertigo and persistent headache had existed for seven weeks before death, together with disease of the lungs. The brain was otherwise healthy, but the fourth ventricle was dilated and presented, lying free, without connection with the ependyma, an oval cyst of about the size of a single almond. The head of the cysticercus could be seen through the transparent coverings. The floor of the ventricle was smooth, but hard and sclerosed.

Creoline. By Dr. Gaudin (*Journal de Médicine de Paris*, December 9th, 1888).—"Creoline is a dark alkaline liquid, prepared from coal-tar, and forming a white emulsion with water. It is a nostrum" (the "Extra Pharmacopœia," fifth edition, p. 163).—Dr. Gaudin states that creoline possesses active hæmostatic properties, through the coagulation of the blood, by the phenic acid which it contains. Uterine plugs, saturated with creoline, have been employed to arrest *post-partum* hæmorrhage. Creoline has also antiseptic properties, which will advantageously compare with other agents of the same kind. In no case has creoline proved poisonous. It is eliminated in the urine (injected daily two grains), without the injurious effects of iodoform, sublimate, or phenic acid. It has no ill effects upon surgical instruments. Dr. Gaudin has employed this substance in obstetric practice successfully.

Note on a (Nervous) Affection, characterised by Astasia (Dysphoria) and Abasia. By Dr. Paul Blocq (*Journal de Médicine de Paris*, December 9th, 1888).—The fundamental characters of this affection are as follow. The patient, being seated or reclining, nothing abnormal is observable. The muscular power, the sensibility, and the co-ordination of the muscles are unimpaired, so that any prescribed movements can be executed. When, however, the patient is desired to stand up or to walk, anomalies are perceived. Sometimes there is an absolute impossibility, the patient would fall if not supported. Sometimes he drags himself along, or what is more frequently the case, the attempt at progression induces a series of inco-ordinated movements; veritable contortions. Nevertheless, other modes of progression than the normal walk, remain, such as jumping, climbing, swimming, crawling on all fours, etc. The principal fact, in short, is the integrity of the muscular power in the recumbent position, and their abeyance in the special actions of walking and standing, whence the terms *astasia* and *abasia* proposed by Dr. Blocq. The course of the affection is variable—it has lasted from three to five months. As a rule recovery takes place, under the treatment applicable to hysterical disorders. The diagnosis is often difficult to make from ataxia, cerebro-spinal meningitis, Friedreich's disease, etc. Both sexes, and all ages, are liable to this form of nervous disorder. The cause is sometimes of an emotional nature, or it may be a slight wound.

Histological Examination of Muscles after Tenotomy. By Dr. Krauss, Breslau (*Fortschritte der Medicin*, December 1st, 1888).—The author found that after the division of the *tendo achilles* there was progressive atrophy of the muscle, to the extent of 51 per cent. loss of weight in eighty days. In the tendon itself an increase of cells and areolar tissue was found, also in the muscles there had occurred an increase of cells and fibrous tissue, together with augmentation of fat cells, and diminution of the muscular fibres. It would seem that there is a relation between these two conditions: the interstitial changes and the muscular atrophy. The human muscles, Dr. Krauss observes, do not undergo after tenotomy such extensive degeneration as those of lower animals. The author is of opinion that subacute inflammation follows on tenotomy. After neurotomy the muscular changes are variable, and resemble those above mentioned as occurring after tenotomy, but attended with a primary interstitial inflammation.

The Pasteur Treatment (*Le Progrès Médical*, November 24th, 1888).—M. Odo Budjwid, of Varsovia, reported that he had treated from June, 1886, to January, 1887, 104 persons bitten by mad dogs, or by dogs supposed to be rabid. The treatment consisted in the inoculation, with spinal cord, for fourteen days. One case proved fatal, not having come under treatment until nine days after the bite. Subsequently M. Budjwid had tried the weaker inoculation upon 193 persons, of which number he registered eight deaths. The intensive treatment of Pasteur was put in practice upon four individuals, who have remained in good health. M. Budjwid has since inoculated 370(!) persons without the occurrence of one fatal case. Eight individuals, who were not submitted to the treatment, had died, in Varsovia or its vicinity. The intensive treatment, Dr. Budjwid infers, is therefore proved, not only to be innocuous, but perfectly efficacious.

Treatment of Diphtheria by Benzoate of Soda. By Dr. Geay (*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, December 9th, 1888).—Dr. Geay draws attention to the successful treatment of diphtheria by benzoate of soda, under the use of which he has not lost any cases. The remedy is given internally, at short intervals, and applied also to the fauces by spray. At the same time the vapour, charged with carbolic acid, is kept by the patient's bedside. In twenty-four hours great amendment is seen, and in from three to four days Dr. Geay says that the patient is out of danger.

Saponaria Alba, an Emmenagogue (*Der Forsschritt*, Genf, December 5th, 1888).—Dr. Blumensaadt recommends the saponaria alba as a most efficient and certain emmenagogue, perfectly harmless in its effects. As a syrup, a tablespoonful is to be given three times a day. The desired result will be obtained in four or five days. It may be given also as an alcoholic extract in doses of $\frac{1}{8}$ to $\frac{1}{6}$ gr.

Safranin a New Test for Diabetic Urine (*Der Forsschritt*, Genf, December 5th, 1888).—Dr. Crismer, of Siege, has investigated the reactions of safranin with grape sugar, and gives the following as a test for diabetic urine. One centimetre of urine is to be heated in a test-tube to the boiling point, with a solution of soda, ley, and the addition of five centimetres of safranin (1-1000). If the colour is discharged, diabetes is present.

Clinical Observation upon Calomel as a Diuretic and Hydragogue. By Dr. Stintzing (*Forschritte der Médicin*, December 15th, 1888).—The diuretic action of calomel has been observed by Dr. Stintzing in twenty-seven cases of dropsy from heart disease, several of these having been complicated with liver and kidney disease. It has a much less diuretic power in the absence of dropsy. Its most effectual influence is seen in valvular obstruction, and in the combination of heart with secondary kidney disease. The removal of fluid from the kidneys under the influence of calomel is much assisted by its effects upon the intestines.

Pyrodine; a New Antipyretic (*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, December 2nd, 1888).—Dr. Dreschfeld submits the following conclusions:—(1) Antipyrine is a powerful antiseptic; (2) it rapidly reduces the temperature of fever patients, and maintains the reduction for several hours; (3) it is readily taken—does not produce nausea; (4) it is equally efficacious in pneumonia as in fevers; (5) it is less suitable to typhoid; (6) it acts equally well in migraine and neuralgia; (7) it should not be administered more than once in eighteen or twenty hours, or it will exert a toxic action; (8) it has acted where other antipyretics have failed; (9) dose forty to sixty centigrammes for adults, ten to twenty centigrammes for infants; (10) it is seldom requisite to give more than one dose in twelve or eighteen hours; (11) pyrodine reduces the number of the pulse; it induces diuresis; (12) it is a white crystalline substance, with very little taste. (Syn. acehyl-phenyl-hydroxine $C_6 H_5 N_2 H_2$ or $C_2 H_3 O$.)

II.—NOTES FROM FRENCH JOURNALS.

By H. R. Hatherly, M.R.C.S.

The Society of Medical Jurisprudence and Public Exhibitions of Hypnotism (*Journal de Médecine*).—At its last sitting the Society of Medical Jurisprudence discussed a question which is at once interesting to the legislator, the doctor, and the public. The question was: "Should public exhibitions of hypnotism be prohibited, such exhibitions having become very fashionable in recent years?" One of the pupils of Dr. Charcot (Dr. Gilles de la Tourette) has depicted a striking tableau of the phantasmagorical scenes which result from these exhibitions of hypnotism. A large number of the women who witness these *séances* are seized with attacks of hysteria; they dream of hypnotisation, magnetic passes, suggestions and other manœuvres which are very fashionable at the Salpetriere school. These women afterwards congregate in small committees to hypnotise each other, and to suggest to each other the most unlikely ideas. Thence arises very justifiable recriminations from the husbands, who find it very unpleasant that their wives should neglect their homesteads in order to follow the Donatos, who always take good care to proclaim themselves *pupils of the Salpetriere*. We

think, with Dr. Gilles de la Tourette, that public exhibitions of hypnotism are open to very serious objections, but we are too strong advocates of individual liberty to conclude that they should be prohibited. In fact, the public are not compelled to take part in the *séances* of Donato, in the same way that the notorious conferences at the Salpetriere are not obligatory on medical students. Besides, if these public exhibitions of Donato are prohibited, there will be an increased desire to witness them, and they will become more popular after than before prohibition. Yes, we hold that hypnotism, recently made fashionable through the school of Salpetriere, is open to serious objections, and that it constitutes a school of hysteria; but on examining the question conscientiously, could we not bring to bear on our physicians the responsibility for what takes place in public? May we not believe that the brilliant professorial lectures of Dr. Charcot at the Salpetriere, conferences to which a large audience of ladies, and of journalists who are not members of the medical profession are invited, have contributed in some degree to create in the public mind a dangerous mania for hypnotism and suggestion? Last year we were much saddened by seeing an enormous canvas representing a woman, a prey to hysterical convulsions, and distorting her frame in the presence of Professor Charcot and his pupils, publicly exposed at the Salon of Painting. We can hardly think that this canvas could have been painted without Professor Charcot's knowledge; we have even a conviction that the eminent professor and his pupils must have devoted much of their leisure time to sittings before the artist. However that may be, the school of the Salpetriere has entered no protest against such a display, made before thousands of spectators, and reproduced in all the illustrated papers. To this point, then, has hysteria been developed in France. Let us, at least, have the courage to admit that if there exist Donatos who trouble the minds of our womankind, the true cause is in the undesirable exhibitions which the medical body may regret and repudiate, but on whom the responsibility must unhappily fall.

Treatment of Wounds by Free Exposure to the Air (*Journal de Médecine*).—Dr. Le Fort, in opposition to the doctrines of Lister, holds that the air exercises no influence on open wounds, and denies that germs of disease are transmissible by the atmosphere. He only admits the transmission of diseased germs by instruments, the hands, etc. The dressing of wounds in the present day requires many precautions, which would prove impracticable in time of war. Dr. Le Fort has endeavoured to demonstrate in an unmistakable manner that air, even that of hospital wards, exercises no evil influence over wounds, and that the prevailing doctrines are erroneous. In order to prove his theory, he has resolved to allow all wounds amongst the patients he has operated on to remain in immediate and permanent contact with the air. He has in his hospital practice—either cured, or on the way to be cured—three amputations of the thigh, three amputations of the leg, an amputation of the foot, a resection of the knee, a resection of the elbow, and many other less important operation cases. All these amputations are healing by first intention, without suppuration, a result which is diametrically opposed to the theory of Lister. Dr. Le Fort merely points out these results, and intends to make a further communication when his observations are more complete. His communication will be awaited with eager interest.

Tylophora as an Emetic (*Journal de Médecine*).—The leaves and roots of this plant are being used, and have been admitted into the Pharmacopœia of India. The leaves are emetic, diaphoretic, and expectorant; they are used in the treatment of gastric troubles in all cases in which emetics are indicated, also in dysentery and catarrh. The dose of the leaves (dried and powdered) is from 1½ to 2 grammes as an emetic; in smaller and frequently repeated doses, it is a cathartic; as an expectorant and diaphoretic, the dose is from twenty to thirty centigrammes three times a day, or oftener if necessary. The root is also employed as a substitute for ipecacuanha; in large doses it is emetic, in small and frequently repeated doses it is cathartic. Its value in dysentery has been long recognised by native doctors, and European medical men are now confirming its usefulness. In Mauritius, tylophora is employed as ipecacuanha, and bears the same name.

Enteroptosis, or Glènard's Disease (*L'Union Médicale*).—It is well known that neurasthenia is a kind of caput mortuum in clinical work, and that it includes all those cases in which the nervous system is deeply implicated, and in which no very exact diagnosis is possible. Dr. Glènard has attempted to define at least one variety of neurasthenia, to which he assigns the name of enteroptosis. Enteroptosis is due to predisposing and determining causes; the chief predisposing cause being the feminine sex and childbirth, as established by the statistics of 200 cases. Another predisposing cause is the pressure of stays, which depress the liver. The determining causes of enteroptosis are exertion and injury: thus the lifting of a heavy weight may give rise to a cracking sensation, accompanied by a sharp pain in the right hypochondriac region, above the umbilicus, and below the false ribs. The effort need sometimes be only very slight, especially after confinements, in order to produce enteroptosis. As secondary causes, the disease may follow long-standing dyspepsia, resulting from gastric atony, typhoid fever, dysentery, local peritonitis, or perityphlitis. In these latter cases adhesions may take place between the ascending and transverse colon. Finally, wasting, or the neurasthenia of convalescence, is alone sufficient to give rise to the disease. The fundamental lesion, which is constant, and which has been found in every autopsy when death has resulted from intercurrent disease, is a falling of the hepatic flexure of the colon. At this point there is no suspensory ligament proper to the intestine; whilst the pyloro-colic ligament attaches the transverse colon to the stomach. The bend of the colon is badly upheld, and falls. The ligament raises the transverse arch towards the centre, thus forming two secondary arches; the first and second portion of the transverse arch communicating by the sub-pyloric orifice. The remaining lesions are the contractions of the digestive tube at the level of the points by which the digestive bends are firmly fixed (gastro-duodenal, duodeno-jejunal, transverse sub-pyloric colon, and left sub-costal sigmoido-rectal colon, rings or orifices). These contractions are produced, according to Glenard, because the digestive tube is raised at intervals, and the angles thus formed are fixed to the posterior parts of the abdomen. There are seven intermediate bends, and six orifices, which are influenced by the prolapsus of the corresponding bends. The true suspensory ligament of the small intestine is formed by the fibrous band, which descends with the superior mesentery in front of the duodenum, when the small intestine is devoid of flatus, and flaccid. The duodenum, in order to pass its contents into the jejunum, has to uphold a weight of at least half a kilogramme; the permeability of the duodeno-jejunal orifice is therefore readily affected. Thus the initial lesion is a displacement of the right flexure of the colon at the least fixed point, followed by static disorders of the small intestine, and entero-stenosis, which is the consequence. But this is not all: it is shown that the transverse colon is attached to the stomach. What is to become of this organ, which has alone to uphold the transverse colon? It will become displaced, and there will be gastroptosis. In fact, the greater axis of the stomach often becomes vertical, is dragged down, and descends into the iliac fossa, and there is frequently, although not constantly, dilatation of the organ. Then it often happens that angular atresia of the gastro-duodenal origin is produced. All this leads to vomiting, dyspepsia, flatulence, etc. The displacement of the stomach is due to the resistance of the intestine by its weight to the upward movement of the ventricle, whilst it contracts and unloads itself into the duodenum. After this, gastric atony may follow. Thus is established a vicious circle, which prolongs the disease indefinitely.

Dr. Glenard lays stress on the frequent biloculation of the stomach, which may account for such symptoms as frequent vomiting immediately after a meal. In enteroptosis it frequently happens that the spleen, liver, kidneys, etc., are also displaced. The anatomy of Glenard's disease may be briefly described as a general descent of all the abdominal viscera, commencing with the right flexure of the colon. The subjective symptoms of Glenard's disease are those of all forms of neurasthenia, and are classified in the order of their constancy, and in the order of their appearance, which concur in the majority of cases.

(1) *Symptoms of Asthenia.*—Debility, habitual lassitude, weakness of the stomach, weakness in the loins. These symptoms mostly appear simultaneously.

(2) *Meso-Gastric Symptoms.*—Tinnitus aurium, sensation of weight, of emptiness, false appetite.

(3) *Gastric Symptoms.*—Flatulence, and accompanying distension, sensation of suffocation, hiccough, gaping, vapours, eructations, pain, cramps, more or less frequent and constant vomiting, pyrosis.

(4) *Nervous Symptoms*, either cerebral or spinal.—Sleeplessness, irritability, sweats, shiverings, hypochondria, melancholia, impotence, headache, giddiness, cough, palpitation, polyuria, cramps, neuralgias, attacks of sub-hepatic pain simulating true colic, etc., etc.

The two first groups of symptoms (asthenic and meso-gastric) are accompanied by four signs, to which Dr. Glenard attaches great importance:—

(1) Awaking at two o'clock in the morning with a feeling of hunger, or colicky pains in the hypogastrium, more or less marked insomnia.

(2) Exacerbation, or the production of discomfort on rising, and at three o'clock in the afternoon.

(3) A constant relation (disguised or otherwise) between the discomforts and the nature of the food (aggravation of the symptoms after partaking of apples, acids, vegetables, wine, milk, etc.)

(4) Irregularity and insufficiency of the motions, constipation, diarrhœa, alternation, special insomnia, and intolerance of milk, are, according to Féréot, the most important of these symptoms.

The physical signs must be obtained by a methodical examination of the abdomen, for which Dr. Glenard lays down very minute rules. The belly bulges, expands, and sometimes assumes enormous proportions. It remains supple on palpation, is moist and flaccid. There is abdominal depression of the hypochondriac regions, showing defective tension of the abdominal walls. About two centimètres below the umbilicus may sometimes be felt a full cord rolling beneath the finger, the cord of the colon. This cord, however, it is almost impossible to make out in obese patients. The signs of displacement of the spleen, etc., are then described. The following test is serviceable in establishing the diagnosis :—The doctor places himself behind his patient, passes his arms under the arm-pits, and placing both hands flat on the lower abdomen, raises it bodily. A sense of relief is immediately felt. If this upward pressure is suddenly relaxed, there is an immediate return of discomfort and painful symptoms. The course of Glenard's disease is slowly progressive. Symptoms of cæcal disturbance, gastric intolerance, and irregular action of bowels, lead to all the oft-described symptoms of neurasthenia. Wasting takes place, and the facial aspect is changed. The condition is always one of misery; and if the pathogenesis is misunderstood, treatment is of little value. Death may ensue from some inter-current disease, or very rarely from inanition. Generally, patients continue in a deplorable condition until the approach of old age, when occasionally a spontaneous improvement takes place. Dr. Glenard does not confuse enteroptosis with dilatation of the stomach or chemical dyspepsia, but only recognises clearly-defined cases. The test of the diagnosis is to be found in the efficacy of the treatment. Appropriate treatment yields excellent results, and permits of the cure of patients who have been treated unsuccessfully for anæmia, metritis, uterine prolapsus, hypochondria, hysteria, and many other diseases for which this variety of neurasthenia may be mistaken. Preventive measures include the wearing of a belt during and after confinement, and the treatment of the earliest signs of weakness or prostration. If the disease is fully established, the indications are :

(1) To raise the intestinal mass.

(2) To increase the tension of the abdomen.

(3 and 4) To regulate the evacuations, and promote the intestinal secretions.

(5 and 6) To nourish the patient, and give tone to the system.

The first two conditions are fulfilled by wearing a low pelvic bandage night and day; the third and fourth by a daily saline laxative; the diet without wine, milk, or any article known to be injurious, will answer the fifth indication; and hydro-therapeutics the sixth. One and a half grammes of bicarbonate of soda, taken with meals, completes the therapeutical treatment.

The German Emperor (*L'Union Médicale*).—The disease from which the Emperor William is actually suffering is considered by French surgeons, whether they are right or wrong, to be a caries of the internal ear, and begins now to form an object of discussion in the Berlin medical societies. Pure otologists and surgeons (amongst others, Bergmann) form two sharply-divided camps; the one boast of the benefits derived from antiseptic irrigation, whilst the other insists on the necessity of trephining the mastoid apophysis, followed by scraping the seat of the abscess.

Local Application of Cocaine in Whooping-Cough (*Journal de Médecine*).—Dr. Veillard recommends the application of a 5 per cent. solution of cocaine to the pharynx and tonsils by means of a brush, in order to diminish the violence of attacks of whooping-cough.

III.—NOTES FROM RUSSIAN, POLISH, AND SWISS JOURNALS.

By Valerius Idelson, M.D., Berne.

Antipyrin as an Anodyne in Normal Labour.—In the Moscow bi-weekly, *Meditzinskoïe Obozreniie*, No. 23, 1888, p. 1033, Dr. M. Z. Kananoff, of Tiflis, says, that, in order to verify Dr. Sielski's statements (*vide infra*), he has tried antipyrin in twenty-one cases of normal labour. The drug was administered either (*a*) internally, in 15-grain doses, two, three, or four times, with half-an-hour intervals; or (*b*) internally, two 15-grain doses, and *per rectum*, a 10-grain dose; or (*c*) internally, one or two 15-grain doses, and hypodermically, two 8½ or 7½-grain doses; or (*d*) *per rectum*, two enemata with 15 and 20 grains. The outcome of Dr. Kananoff's experiments is this: 1. The action of antipyrin is by no means constant (only in six cases good anodyne effects were obtained; in the remaining fifteen patients the remedy proved to be entirely inert). 2. In a considerable proportion of cases (in seven out of twenty-one), the drug shortens the duration of uterine contractions and lengthens the intervals between them. 3, Its administration involves the necessity of more frequently rupturing the fœtal membranes (5 cases). 4. It gives rise to an increased *post-partum* loss of blood (in *six* cases a *profuse* flooding occurred; "in many other patients the bleeding was more considerable than in those delivered without the drug"). 5. In view of all the facts, antipyrin should not be urged in labour. 6. It does not seem, however, to produce any unfavourable influence on the infant.

[In the Polish *Wiadomosci Lekarskie*, No. 10, 1888, p. 289, Dr. F. Sielski, of Lvov, Austrian Galicia, describes four cases of labour where he most successfully employed antipyrin in one-gramme doses, repeated every couple of hours. The administration was invariably followed in a few minutes by an almost complete cessation of pain, while uterine contractions remained as strong as before.—*Reporter.*]

Ectopia Vesicæ Urinariæ.—Dr. Stankiewicz (pron. "Stankevitch," a Polish name), of Warsaw, records (*Wiadomosci Lekarskie*, October, 1888, p. 130) a remarkable instance of extroversion of male bladder where surgical interference was crowned with most gratifying results. The patient, a robust, powerfully built man, æt. twenty-six, applied to the author with urgent requests to relieve, by any means, his miserable condition, which had become absolutely intolerable for him. On examination, a typical ectopia was found, the penis being very short and flattened, but the testicles were situated normally. There was a left-sided hydrocele, while the whole inguinal regions, as well as the scrotum and penis, were covered with numberless excoriations and erythematous patches, caused by an incessant flow of the urine. A whole series of plastic operations (fifteen in number, in the course of seven months) proved to be necessary to cover the defect in the abdominal wall, every one of which was associated with "unheard of (*Nieslychanie*) difficulties for the surgeon, and most agonising pain for the patient, who could not be kept under the influence of chloroform, since the latter invariably gave rise to an intense excitement, making impossible any manipulations." The flaps for closing in the bladder were made of the adjoining lateral abdominal skin, while the upper moiety of the urinary tube was formed of the scrotal integuments. The last operation over, the man found himself able to hold a half of tumblerful of his urine when lying, but on his resuming an erect posture, the vesical contents immediately escaped. To remedy the condition, Dr. Stankiewicz invented a simple, but ingenious appliance, which consisted of a small light pad placed under the penis, and secured to a belt round the waist sufficiently tightly to produce a pressure on the root of the urinary tube in direction from below upwards (that is, to close the lumen of the tube). On removing the pad, the urine would flow; on re-adjusting it, not a drop would escape. When shown to the Lvov Meeting of Polish Practitioners, the patient was quite well and felt most comfortable. A similarly successful case had been demonstrated by Dr. Szeparowicz at the Cracow Meeting.

Suggestive Chloroform Anæsthesia.—In the *Correspondenz Blatt fuer Schweizer Aerzte*, January 1st, 1889, p. 30, Dr. E. Haffter (the editor), of Frauenfeld, writes, that, according to his experience, such persons who are sensitive towards a hypnotic suggestion, very often fall asleep immediately after the adjustment of a chloroform mask, accompanied with some usual soothing words (that is, before any chloroform has been given). Starting from that observation, he now frequently resorts to hypnotisation after the following method which proves successful in his hands, and which he, correspondingly, recommends to the profession. Having placed the patient in a sitting or recumbent position, he holds the mask before his face and orders to shut the eyes, to breathe quickly, and to as quietly sleep. The effects desirable are said to be obtained sometimes most rapidly.

Dr. Haffter's statements are corroborated by Dr. Wilhelm Roth, of Fluntern (*l. c.* p. 29), who has recently employed, in a quite accidental way, the "*pseudo-chloroform-narkose*" in a case of subcoracoid luxation, referring to an anæmic and highly-nervous gentleman. Having addressed to him some assurances to the effect that he "will fall into a quiet sleep under the influence of chloroform and will feel no pain whatever," the doctor commenced the administration of the drug. All of a sudden, after a couple of whiffs, the gentleman began to make deep and even respiratory movements. Being rather alarmed by the circumstance, the author at once discontinued the inhalations and removed the mask. The patient was found actually sleeping as soundly and as quietly as possible, his pupils being widely dilated and somewhat sluggish. Without any delay, Dr. Roth proceeded then with reducing the luxation, but all his manipulations failed on account of an intense muscular resistance. Feeling disappointed, he dropped a cursory remark to some persons standing close by, that "the reduction could be effected only in the case of a relaxed state of muscles." To his extreme surprise, scarcely those words had been uttered, "the muscles as if by magic became quite soft and flabby," and the reduction could be completed "in a jiffey." The doctor's order to "wake up" was similarly obeyed instantly. The gentleman showed a complete amnesia: he stated that he had not felt any pain during the manipulations; nor could he recollect anything about the doctor's involuntary suggestion concerning the "relaxation."

IV.—SKIN DISEASES.

AN APOLOGY FOR A NEW CLASSIFICATION OF SKIN DISEASES.[1]

By C. M. Campbell, M.D., C.M.

I use the word apology in its modern and colloquial, as well as in its old and classical sense, for certainly any addition to the existing plethora of classifications must seem to many an unnecessary infliction, if not, indeed, an impertinence. But while fully conscious that a strong justification for such an attempt is imperative, I am constrained to make it, simply and solely because I can find no restful satisfaction in any of the classifications that I have yet had an opportunity of studying. And here at the outset I would disclaim any pretension to having finally interpretated and satisfactorily stereotyped the solution of the vast, varied, and I will add, paradoxical question. All that I aspired to, has been to construct a chart, as little inconsistent as possible, by grouping the most well-defined lesions so that their positions on it may at once convey to our minds one or more elementary pathological facts concerning physical elements, gold, or platinium, or oxygen, one always identical in every characteristic, whenever they exist in a state of purity; and so the chemist, working with fixed elements, can predicate, with certainty, the result of their re-actions. But a disease is very different, no two examples are identical, and refusing to be bound by human definitions, however adroitly constructed; the combination of phenomena which to-day we have, to our own satisfaction, labelled so-and-so, has, by to-morrow, given place to a fresh combination, which we are fain to label something else. Again, the phenomena held to be characteristic of more than one named disease may be evident on the same spot at the same time, which complex combination the eager nomenclaturist will tabulate in portentous length. Moreover, a lesion may begin in one structure but pass to another, the effect upon the latter far transcending in importance that upon the former, so that the *fons et origo* is apt to be obscured and unrecognised. Such being the objections and difficulties, the question naturally arises, "Why attempt classification at all?" To which I would reply, "Why, indeed, unless we thereby get a clearer conception than we otherwise should, first, of the anatomical site of the initial lesion of any given disease; and, secondly, of the fundamental character of the evolution of that lesion." If our classification accomplishes this, however imperfectly, it has certainly established its *raison d'etre;* if it, or any other, fail to do so, I confess that I cannot see its right to exist.

CLASSIFICATION.

	Site of Initial Phenomena in EPIDERMIS.				Site of Initial Phenomena in DERMA.
CLASS I.—Hyperæmiæ.					
a. Capillary Fluxes					Erythema (many varieties), Eczema, Dermatitis, Furunculus, Rosacea, Superficial Abscess
b. Venous and Venoso-lymphatic Stases					Œdema, Cyanosis, Scleroderma, Gangrene, Purpura, Scorbutus, Myxœdema, Ecthyma, Nævus
CLASS II.—Neuroses.					
a. Trophic					Herpes (Zoster, etc.), Neuritic, Erythemata, Pemphigus and Decubitus, Urticaria, Prurigo, Alopecia Areata (one form of)
b. Sensory					Pruritus, Neuralgia
CLASS III.—Developments and Retrogressions.	*Cornification:*	*Pigmentation:*	*Prickle Cells:*	*Glands and their Products:*	
a. Hypertrophic	Ichthyosis, Lichen, Cornu, Trichosis, Onychosis	Sphelides, Lentigo, Chloasma, Nævus (Non-vascular)	Verruca, Condyloma	Comedo, Seborrhœa, Hyperidrosis, Steatosis	Myoma, Fibroma, Angioma, Neuroma, Lipoma, Zanthoma, Keloid, Rhinaphyma
b. Atrophic	Alopecia Pityrodes	Albinism, Leucoderma	Pemphigus	Leioderma, Zeroderma, Anidrosis, Asteatosis	Alopecia Senilis
c. Vicious	Psoriasis, Pityriasis	Icterus, Morbus Addisonii, Argyria	Epithelioma	Milia, Acne, Sycosis, Molluseum, Idroses(various)	Sarcoma
CLASS IV.—Invasion of Micro-organisms.					Syphilis, Tuberculosis, Scrofuloderma, Lupus (varieties), Anthrax, Erysipelas, Impetigo, Pemphigus (one form), Lepra, Endemic Furunculus, Rhino-scleroma, Exanthematous Fevers, Elephantiasis
CLASS V.—Gross Parasites.					
a. Animal	Pediculi (various). Acari (various), Cimex, Pulex, Obstrus, Leptus Autumnalis, etc.; Cysticercus, Echinococcus, Filaria Medinensis, Filaria Sanguinis Hominis, etc.				
b. Vegetable	Tinea: Favosa, Achorion Schönleinii; Tonsurans, Circinata → Tricophyton Tonsurans; Sycosis, Microsporan Martagraphytes; Versicolor, Microsporan Furfur; Alopecia Areata (one form of), Microsporan Andonini				

them. To fulfil such an essay completely is, I am well aware, impossible, enough for me if I can sketch a scheme which, with all its shortcomings and plans, may command itself to common sense, as a provisional help to a most perplexing study. A perfect classification is, in our present state of ignorance, an unrealisable ideal: shall we then abandon all attempts to evolve order out of class? Certainly not; but let us rather do the best we can, with the imperfect and scanty knowledge we as yet possess, conscious of our blindness and our faults, and, in all humility, merely hoping that our efforts may prove provisionally useful, until more light shall shine upon the dark places of dermatological science, till the crooked shall be made straight, and the rough places plain.

The reasons why all classifications must necessarily be imperfect are not far to seek. In the first place, when we name a disease, we do not thereby imply that it is a definite universal entity, like one of the

Some classifications are deserving of our most respectful attention, even though we cannot see our way to adopt them; but there are others again which recall to mind a work upon "English Dogges." by the very learned, but very unscientific founder of Caius College, Cambridge, who tabulated a distinct class, or breed, or species of dog, which he designated "the Mooner" (*Caius Lunarius*), all on account of "a quality, in mine opinion, strange to consider, of bawing and wawing at the moone." But it is surely little, if any more scientific, to place widely different dermatoses in our class, merely because they are characterised by a single common feature, or present certain morphological analogies. Thus we find, say a class headed "Pustulæ," which would include the minute traumatic abscess caused by the presence of a thorn-point, or splinter, acne, scabies, furunculus, impetigo, variola, and various syphilides; or if not, why not, for they are all "pustulæ,"

[1] An Abstract of a Paper read to the Willan Society of London, March, 1888.

literally and truly, although fruit of very different trees? Does this arrangement then afford us any elementary information as to the etiology, pathology, or significance of any one of these lesions, of which pustulation is the *only* feature common to all? What should we say of the zoologist, who placed in one class a bat, a bird, and a beetle, because all possess wings; or a cow and cuttlefish, because both have eyes and a tough skin? Yet if we elevate vesiculation, pustulation, or exfoliation, to the position of representing the essence of all the lesions which are classed under them, are we one whit more scientific? I venture to think not. Other classifications again, in my humble opinion, are all too diffuse and complex, drifting away from the essential and salient characteristics into endless minutiæ and hair-splitting; piling up a portentous catalogue of compound names, which the bewildered student tries in vain to recollect, or even to understand.

As has been said, the name of a disease does not represent an invariable entity, but merely denotes the existence of certain abnormal phenomena, co-existing in one spot, in limited proportions, at a given time. For example, by the words "erythema pernio," we express a concatenation of phenomena induced by cold—viz., paresis of the *nervi vasorum*, with resulting hyperæmia, and stasis, but not rising to the height which we should designate dermatitis, with more or less pain, occurring simultaneously in a given area. Some names are thus easily defined, but others are most difficult to define in terms which would be accepted by every dermatologist. It is, therefore, of great importance in framing a classification, that every effort should be used to employ only the simplest names, which convey the most definite and least variable pathological meaning, letting it be understood that the one broad title includes all the varieties, with their different qualifying descriptive adjectives. A chart should not aim at being an epitomised manual, and those which have endless strings of adjectives introduced to denote every conceivable variety, lose both crispness and breadth, to use artistic expressions, and fail to impress the understanding of the student. Doubtless, from an academic point of view, it is desirable that every combination of phenomena, which is sufficiently differentiated from all other combinations, so as to be clearly discernible, should be named and placed in a complete scheme of classification. But admitting this, I think that the fewer adjectives we introduce the better, so as to keep the scheme as simple as possible. Adjectives implying varieties have their proper place in the pages of a descriptive manual, rather than on a chart. And now I must at once admit that, in the scheme which I venture to lay before you, some names are placed in a certain position which might have been placed elsewhere. While, in general, professing to make the position of any given disease depend partly upon the anatomical site of initial lesion, I have not been consistent in so doing. Where the secondary phenomena have dwarfed the initial into insignificance, I have felt constrained to place the name of the disease where, clinically, we should expect to find it.

Take, for example, eczema, the initial lesion of which may be in the feebly vitalised prickle cells of the epidermis, but which owes its most prominent characteristics to hyperæmia and the resulting phenomena. And you must remember that a very large number of epidermoses involve the derma, also sometimes causing hyperæmia, as in acne, psoriasis, etc. Dermoses also may secondarily affect the epidermis, so that the position of some of the lesions on my chart are, undoubtedly, open to criticism. Leucoderma, for example, might have been placed as a tropho-neurosis of the epidermis. Still, I have endeavoured to keep to the rule of placing each in the division in which is the *fons et origo mali*. Now, what are these two grand divisions? They are simply the anatomical ones. 1. The epidermal structures, with their appendages, glands, hairs, and follicules. 2. The derma, including the papillæ, capillaries, lymphatics, and nerves. And I feel very sure that we shall lose nothing, but on the contrary gain a great deal by always keeping in mind this question, "*In which of the two is the initial fault?*" Keeping this great anatomical division in mind, I must pass on to consider the classes, of which I see no reason for having more than five—viz., 1. Hyperæmiæ, with its sub-classes, capillary congestions, and venous stases. 2. The neurosis. 3. Abnormal developments and retrogressions. 4. Invasions of pathogenic micro-organisms. 5. Lesions caused by parasites, animal or vegetable.

Now, I venture to maintain that there is no known form of skin disease which cannot with perfect propriety be placed under one of these five classes, although I frankly admit that we may be somewhat puzzled as to which of these may be its proper one. Some on the chart, I daresay, you may think misplaced, but I can only assure you that I have placed each where you see it, not from whim or prejudice, but because I had what I considered good reason for so doing. Of course I cannot take up the pathology of each one separately, yet I should really require to do so to justify my plea; but as I find that my notes upon them take about three hours to read, I think that you will excuse me, as well as yourselves, from such an ordeal. I shall, therefore, content myself with a rough review of these five classes, and then leave it to you to question me concerning the faults and inconsistencies of my scheme.

Now, first as regards the hyperæmia—a large and important class. Congestion of the Papillæ may arise from paresis of the nervi vasorum, due to irritants from within or from without. The congestion may run on to stasis, exudation, diapedesis, and the formation of pus, to venous, or venoso-lymphatic stasis, and the latter, when established, tends to become chronic, and to perpetuate or excite afresh the arterial flux, all of which phenomena are common to the diseases in this class.

I now turn to the neuroses, and would remark that the nerve fibres which have been traced by Unna and others into the prickle cells of the epidermis, appear to be concerned with the functions of those cells—viz., cornification—and not with common or special sensation, so that, strictly speaking, many of the epidermoses may be initiated by abnormal action or paresis of these nerves. We have, besides, other lesions due undoubtedly to grosser forms of paresis, as well as to irregularities of function of the nerves of the derma, whether sensory, vaso-motor, or sympathetic.

I pass next to developments and retrogressions, which require little explanation. I have made three sub-classes—viz., hypertrophy, atrophy, and vice. I use the word vice to denote pathological formations of tissue which are different to mere increase or decrease of normal tissue.

As regards the fourth class, I daresay you may not all agree with me that a specific contagium vivum is the *fons et origo mali*. Still, when I know that in many of these diseases the lesions supply material which can be cultivated on sterile blood serum in an incubator *ad infinitum*; that a long series of plates or tubes can be inoculated one after the other, from each in succession; and that from the last of the series we can obtain micro-organisms which, when inoculated in a living subject, reproduce the original disease, I am forced to the conclusion that this living micro-organism is the real and essential *materies morbi*. This has been done with anthrax by Pasteur, with erysipelas by Fehleisen and by Ranvier; with the Pendjeh sore by Cunningham; with glanders by Strück and by Bouchard. It has been proved with regard to syphilis, all but the inoculation upon a virgin subject, for as you may well suppose no man is found willing to adopt this certain method of acquiring it, however ready he may be to run the risk of so doing in another way, and as animals will not take syphilis the final test is wanting; but as the bacilli have been noted and cultivated, always presenting the same characters as their progenitors, the inference is very strong that here, also, we have found the contagium vivum. Indeed, we can reason the matter out another way, and this holds true of all the exanthemata as well.

We are all agreed that when one person affects another something of the nature of a poison passes from the one to the other. Now what is this something? It is very minute, so that a mere scratch with an infected needle will convey it. Well, a poison must be either inorganic, such as arsenic, or organic, such as strychnine, or a ptomaine, as rattlesnake poison, or it must belong to the bacteria. I do not know of any other forms of poison. Now all these forms, except the bacterial, have this common characteristic which distinguishes them from it—that you cannot regain from the poisoned subject more of the poison than you put in; you may probably recover less, perhaps as much, but certainly not more. But inoculate a man with the $\frac{1}{100}$th of a minim of variola pus, and in a given number of days your poison will have reappeared multiplied a millionfold. Every minim of pus from the pustules of your subject is capable of inoculating one hundred men more, so that your original poison has increased in quantity amazingly. In other words, the bacteria have reproduced themselves in myriads, and a thing which is capable of reproduction possesses that which no mere chemical or alkaloid has—life. And, as I have already said, we can cultivate many varieties of infective bacteria away from the body, watch them through many generations, and reproduce them, with all their pathological consequences, in a fresh living subject.

Finally as regards the parasitici. I have not thought it necessary to carry the two anatomical divisions of epidermal and dermal into this class, for that division now ceases to be a practical aid to understanding. The organisms in this class are more coarsely obvious than in class iv., some being visible to the naked eye, and all being so under comparatively low powers of the microscope.

Such, then, is broadly and briefly the scheme which I venture to propound for a practical working classification of skin diseases. I hope you will by your criticisms aid me in correcting its many imperfections, for I can honestly assure you that none of you can be more conscious of its shortcomings than I am.

V.—SELECTIONS FROM CONTINENTAL JOURNALS.

By our Spanish Correspondent.

The Falkenstein Consumption Cure (*Revista de Ciencias Médicas*).—Not far from Frankfort, in a sheltered valley of the Taunus range of mountains, lies the little village of Falkenstein, amid the most charming scenery, completely isolated from the world, and yet within easy reach of the city, itself one of the cleanest and healthiest in Europe. There Dr. Dettweiler has established a home for the treatment of consumptives, on the system devised by Brehmer, and carried out by him for many years past at Görbersdorf in Switzerland. The method is simplicity itself: free exposure to pure cold air, and the proscription of all drugs which have gained any reputation in the treatment of the disease. Then the patients are to be lodged in an establishment devoted solely to their reception, under "a benevolent despotism," a discipline of mingled kindness and firmness; the building or buildings being located near to, but not in, some healthy mountain village, well sheltered from the wind, free from dust, and far from the friction and excitement of ordinary hotel life.

Except under medical dispensation all must be out of bed by 8 a.m., the first breakfast of milk, cognac, and bread being served in the open air at a quarter past that hour; then the patients sit in comfortable arm-chairs with an awning above them, out-of-doors if the weather be fine, but in covered galleries when there is rain, and these are only protected by canvas blinds in front when it is very bad indeed. The greater number of the cases pass twelve hours daily in the open air, sufficiently but not too warmly clothed, breathing the fresh air, whether there be sunshine, rain, or snow. In the winter they retire to their rooms between five and six in the evening; but, whatever the season may be, they sleep with the windows half open, and with their arms lying outside the bedclothes. At the beginning of the treatment—except in the slighter cases—absolute rest is enforced; the patients sit in the gardens, or within the galleries, in their chairs, each with their own private spittoon—for it is forbidden to expectorate on the ground, or into one's handkerchief—passing the time as they please, in reading, quiet conversation or dozing the hours between the meals away. Then, as the strength improves, exercise, not exceeding for a quarter of an hour a day, is permitted; afterwards three times a day, and eventually for longer periods, but still with regulated intervals of repose; rest, with pure air, or rather in the open air, being the key-note of the treatment. There are three meals a day—meat, eggs, pulse, bread, butter, conserves, creams, wine, and liqueurs. Cheese is forbidden, but the patients are invited to take milk and brandy between meals whenever they care for it. Cough is checked by sipping a little very hot or very cold water, and they are taught to cough only when it is necessary to expectorate, and then only after thorougly filling the chest with air. Night-sweats are checked or abolished by friction of the body and limbs, either with a dry cloth, or a felt glove moistened with alcohol, night and morning. Two drugs are alone made use of: antipyrin, if the temperature do not recede under complete rest; and a small dose of morphia if the nights are restless. The carrying out of this system requires extreme firmness and vigilance on the part of the medical attendants. "I am the head master of a school," said Dr. Dettweiler, smilingly, to the author, "and the work is very hard, but I turn out absolutely cured twenty-five per cent. of my scholars!"

The Microbe of Hydrophobia. By Dr. Ferrán, Barcelona (*Revista de Ciencias Médicas*).—"In the publication of scientific discoveries one cannot be too careful to verify every step in the processes employed, and I only venture to make known my own," says the author, "after having examined and re-examined in every stage of my investigations with the most scrupulous care. It may seem, perhaps, that these means were after all extremely simple, but the most difficult problems are often happily solved by the very simplest analysis, the apparently insuperable by the most primitive."

The microbe of rabies exists chiefly within the migrating cells of the plasma-spaces of the nerve centres, and in similar cells found in the cerebro-spinal fluid; and the mode of securing these is as follows: As soon as a dog suffering from the disease dies, the skin and muscles should be dissected from the back of the neck, so as to expose the atlo-occipital articulation; the carcase should then be placed on an inclined plane with the head downwards; then, with the thermo-cautery, an eschar should be made over the articulation, and with a sterilized bistoury the sheath of the cord is opened through the burnt space. The fluid is then collected in small spindle-shaped tubes with capillary ends, which have been, of course, sterilized when made, and the points melted, these are broken off at the moment of filling, and at once resealed. The rachitic fluid of a single dog will fill a dozen of these little tubes; when charged they are placed horizontally in a box, and left for some time in complete repose. After a few days, at a temperature of 20° Cent., one sees in some of the tubes a pale line of deposited cells with one or more white points, extremely small, yet still visible to the naked eye; these are colonies of the microbes in question. The groups are always few in number, and only one out of many tubes may contain them. This explains why animals may be inoculated with the cerebro-spinal fluid of an unquestionably rabid dog, and yet not acquire the disease. And is probably due to the paucity of the pathophoric cells which contain the microbes, or that these latter have not always vitality enough to make their way through their walls. By succussing the tubes strongly the colonies can be broken up, and the fluid becomes opaline; whilst healthy lymph from the same source, and treated in the same way, undergoes no change whatever.

The activity of the poison used has been in every case proved by inoculation in series of dogs and rabbits. A drop from one of the shaken tubes shows cells filled with sarcinoid masses of coccus and glomerules separated therefrom. In other tubes this is not seen, but agglomerated microbes bacillar in form, which the author believes to be a transitional condition. These germs are easily cultivated in slightly alkaline broth, in gelatine and agar-agar with or without glycerine. The first cultivations should always be made in broth, and be afterwards transferred to solid media. Their liquefying action on the latter is slight, but in some cases it was complete, and may have been owing to some defect in the gelatine itself. In broth, after five days at a temperature of 20° Cent., there were numerous globular or irregular deposits at the bottom of the flask; in some it adhered firmly, like a mycoderma to the glass; but in most a vigorous shake was enough to make the whole fluid opalescent. It would seem that there is some diastatic difference in these growths, but their pathogenic power is alike; this was proved by physiological reactions—by the fatal inoculation of other animals.

He has succeeded in isolating the microbe from the spinal fluid of rabbits dead through the disease communicated from dogs by corneal incision, and in others inoculated in series for the anti-rabic treatment. For instance, amongst twenty tubes filled from one of the latter, two or three have been found to contain the specific microbe. It is very easily stained by gentian-violet and aniline-red—in diluted alcohol especially so.

Pathogenic Action.—One of the incubating flasks is shaken so as to diffuse the germs; then a drop of the fluid is allowed to fall into both eyes of a number of dogs, and a slight scratch is made in each cornea. The little wound heals very quickly without inflaming, although it has been the channel through which the poison has entered, and for eight or ten days the animals seem perfectly well; then they become suddenly ill, and emaciate rapidly; are attacked by general paralysis, and, after two days of feverish hyperthermia, die exhausted. The eyes are throughout free from inflammation. It should be added that some of the same group of dogs become ill, but do not die, and that others may even be quite unaffected.

The nerve-pulp, as well as the cerebro-spinal fluid of the animals which die will produce in indefinite series the typical rabies of the laboratory. But the ordinary tests of cultivation and microscopic examination have failed to show in any case the presence of the microbes in the humors and tissues of the animals killed by keratic inoculation with the artificially-cultivated germs. On the other hand, hypodermic injections in large doses (*de dosis masivas*), twenty to thirty cub. cent., of the sediment in the cultivating flasks have not the slightest effect on the animals so receiving it; no more, indeed, than if one had injected as much pure water. But there has not been time enough to decide if no remote effects follow. It should be observed that all these experiments were made with cultivations between the 4th and 10th in series, so that the effects of the germs contained in the cerebro-spinal fluid itself dropped into the first flask, should be eliminated. And it has been proved by experiment that this fluid has very little poisonous action. Nevertheless, it cannot be denied that this fluid is more active *when injected* than the cultivated microbes from the original tubes. This leads one to believe that the microbe of rabies during its intercellular life may undergo some modification which renders it less fit for subsequent segmentation in cultivating media. Apart from this, the success of the first trials therewith depends upon the presence in sufficient numbers of the phytopherous cells in which the microbes may multiply freely after, probably, the digestion of their envelopes (*despues de la digestiou probable de la envoltura célular*).

"Therefore, this virus, in artificial cultivations, causes the death of dogs after corneal inoculation in minute doses, but is harmless when injected in large doses hypodermically if it has been previously cultivated in rabbits; precisely as happens with the poison from the dog and from the rabbit, as we," says the author, "were the first to discover."

Inoculations *en masse* of the recent nerve-pulp of rabid dogs do not always kill rabbits, nor will the same procedure with that of mad rabbits prove fatal to human beings or to dogs, but it will to other

rabbits. The author believes that the microbe has no power of independent growth or even existence apart from what he terms the phytopherous cells (*células fitóferas*), in which it lives in its primary host; that in the cultivating media it still finds its pabulum in their "digested envelopes;" but, on the other hand, that it is only the free (and dying?) microbes which are endowed with the terrible power of communicating the disease. He gives, too, to the encysted microbes a mysterious antagonistic power over the free, and explains the fatality of the scratched corneal or meningeal infection by a theory that more free microbes can so enter than encysted ones; and the harmlessness of injections *en masse* by the greater number of the benign cells which then accompany them.

[In a future paper he will discuss the prophylactic powers of the microbe.]

Les Inoculations Anti-rhabiques (*Journal d' Hygiène*, Paris).—The chagrin of M. Pasteur at the refusal of the English Government to contribute to the funds of his hospital is natural; but, as the value of the procedure itself is yet doubtful, that of the institution is *à fortiori* more problematical still, and it seems unlikely that its waning prestige will endure as long as the life, much less the fame, of its founder. In a discussion of the question at the Academy of Medicine of Paris in October last, several distinguished men took part, the ideas of M. Pasteur having the support of MM. Grancher, Brouardel, Vulpian, and Charcot, and were opposed by MM. Jules Guérin, Farvel, and Peter. As a *précis* of the speeches, one may say that those of the first group were more remarkable for enthusiasm and declamatory powers than dependence upon statistics and incontrovertible facts. Vulpian vivaciously repeated the phrase which we have heard many times before: "La rage, cette maladie terrible, a enfin trouvé son remède!" And Charcot: "M. Pasteur peut marcher la tête haute, ... sans s'en laisser détourner un seut instant par les clameurs de contradiction, ou par les murmures insidieux du dénigrement!" Quite so; no one can doubt for a moment that M. Pasteur thoroughly and honestly believes in the reality and worth of his system. If it be an illusion, it is still that of one of the most honourable and most modest of scientific men. But declamation is not argument, and the logic of ascertained and recorded facts cannot be swept away, even in a whirlwind of impassioned words.

Jules Guérin replies: "The experiences of M. Pasteur belong to an *artificial* rabies, purely theoretical; and the method itself is but one of theoretical prevention. It is one thing to nip rabies in the bud, another to cure it." M. Peter: "The rabies of the dog is convulsive; communicated to man, it is still convulsive. The rabies of the rabbit is paralytic; inoculated in man, it should be paralysing also, and the paralytic form of hydrophobia, once so rare amongst men, has become common since the anti-rabic inoculation, especially since the use of the intense method, which has replaced the first, which was believed to be so perfect."

"Never have so many people died from hydrophobia as since the introduction of this method, which was to have saved them all. M. Pasteur is not the successor of Jenner; that which *he* inoculated was the natural virus of cow-pox—a disease, it is true, but one which could never be a source of danger. That which M. Pasteur inoculates is the virus of charbon, of erysipelas ever replete with perils. Therefore, it is a strange abuse of language to apply the term *vaccination* to a procedure so hazardous and uncontrollable. It is not necessary to reproduce here the reports of the many fatal cases amongst patients under treatment, and those who had been discharged as cured; nor, on the other hand, to more than refer to the way in which tipsy people, hysteriques and monomaniacs had been subjected to this dangerous treatment for a disease from which they were absolutely free, and how their names swelled so enormously the lists of the 'cured.'" But it is not England alone which has proved incredulous or ungrateful: Florence has not only declined to contribute to this Paris institute, but has refused the advantage of having an Institute Pasteur of her own. In an exhaustive report presented to the municipality by M. le Pr. Michelacci occurs the passage: "One cannot recognise as really demonstrated the unquestionable efficacy of the method, nor the absolute absence of danger."

As a practical commentary, the following incident may be related:—At a recent meeting of the Board of Health of the Seine, M. Pasteur reported that cases of hydrophobia amongst human beings were constantly increasing in Paris. On the 19th of June sixteen persons bitten by mad dogs presented themselves for treatment, eleven being from the city itself. Under these circumstances, he felicitated the Prefect of Police on the measures he had adopted for at once seizing all masterless dogs, and even those with inscribed collars which were not led by a string.[1] But it is somewhat remarkable to find the *savant* who had discovered a certain cure for rabies approving of means for the destruction *per fas et nefas* of all the dogs they could get hold of! At the same meeting the Prefect reported that he had received many letters begging M. Pasteur to describe for their information the earliest symptoms of rabies amongst dogs and cats, and how they should treat them. To the great disappointment of the Board and the public, M. Pasteur, ever faithful to the principles of scientific exactness, replied: "That it was not possible to clearly define the characteristic symptoms of rabies, for even veterinarian experts sometimes made an erroneous diagnosis!' An opinion so reserved, and a *modus agendi* so unexpected, hardly seem of a nature to secure the reception by posterity of this legend of the curability of hydrophobia.

[1] Since the publication of this police order, about 100 dogs a day have been sent to the depôt, where they are asphyxiated in about three minutes, in an iron chamber filled with coal-gas.

VI.—OBSTETRICS AND DISEASES OF WOMEN.

The Value of Hysterorrhaphy as a Primary or Consecutive Operation in Uterine Displacement (*Transactions* of the New York Academy of Medicine).—Dr. C. C. Lee read a paper with this title. The operation, he said, was comparatively a new one, but was not difficult, and it gave relief in a class of cases which had been hitherto entirely intractable. It consisted in sewing a displaced uterus to the anterior abdominal wall. It had first been done as a supplementary operation, after the performance of ovariotomy. Of late it had become a primary operation for the relief of severe cases of prolapsus and retroflexion, and was thus somewhat allied to Alexander's operation in its object. It took the place of the latter, and also gave relief in a class of cases in which the latter was excluded from use. Omitting any allusion to a large number of cases in which he had done the operation as a secondary one to ovariotomy, the speaker then gave an account in detail of six cases in which he had done the primary operation with complete recovery in four of them. All were cases of retroflexion with adhesions, some accompanied by lacerations incidental to childbirth, others by prolapse of the tubes and ovaries, salpingitis, and dysmenorrhœa; others by severe hæmorrhages. All these women had been in a miserable condition from constant suffering, which ordinary measures in the hands of the best physicians had entirely failed to relieve. He had found the operation easier than that for the removal of the appendages. It relieved conditions that were fully as serious as those for which the latter was performed. In no instance had he had a marked rise of temperature following hysterorrhaphy. At the present day the operation might be considered a safe one. In making the sutures he used fine Chinese silk. The suture was passed, not through the vascular fundus of the uterus, but on each side of the fundus, through the proximal ends of the broad ligament, and including the round ligament; and in making the suture through the anterior abdominal peritoneum he included the subperitoneal fat as well. This suture he left in. He much preferred the Chinese silk to silk-worm gut, catgut, or silver wire. In breaking up the adhesions he used only his fingers. The only other radical procedure which gave relief in the same class of cases as hysterorrhaphy did was the method of stretching out the adhesions by massage, as now practised in Europe. As for Alexander's operation, that was of value only in the cases where the uterus was freely movable.

Dr. Howard Kelly, of Philadelphia, thought the operation a valuable addition to our resources, but that it must not be done until all ordinary means had been tried without success. The operation was a safe one. Of ninety-two operations of which we had record, only one had proved fatal, and that had been in his own hands. In this case the intestine became adherent at the point where the suture was passed, and death took place from ileus, in spite of a special operation for the repair of this accident which he had done. He considered the mechanical basis or principle of the operation unexceptionable. The merest thread was sufficient to keep the uterus tilted forward in a position where the pressure of the abdominal respiratory rhythm came upon it from behind and kept it there. He thought there were four conditions in which the operation should be employed: 1. Where Alexander's operation had failed to relieve. 2. Where there were adhesions binding the uterus in retroflexion, unless the operator preferred the method of stretching them by massage, and here he thought an effective pressure could be brought to bear on the uterus from the fingers in the rectum. 3. Where the uterus was prolapsed. 4. When a tumour had been removed; here it was always best to make sure of a restoration of the uterus to a normal position. In operating, the incision should be made as low as possible, and the uterus attached low, to avoid the danger there would otherwise be of the intestine becoming caught between it and the abdominal wall. When the broad ligaments were stretched out into a fan-shaped vascular curtain he lifted them out and reached back so as to get a part that was not vascular, sometimes catching his suture through the ovarian ligament itself, which raised the ovaries on either side at the same time that it drew the uterus forward.

Dr. Paul F. Mundé agreed with Dr. Kelly that it was safe enough to be used without hesitation whenever it seemed indicated. But he also agreed with him that, in case the adhesions which bound the uterus posteriorly were very thick, it was one of the most difficult of operations, and in other cases might on that account be impossible to do. He thought we must in the future learn to recognise the latter class of cases in advance.

Dr. H. J. Boldt discussed the method of dealing with these cases by massage and exercises as practised by Brandt in Sweden. He remarked that great care must be used in making a diagnosis previous to beginning this form of treatment, else great harm might be done, as in case of pyosalpinx being present. In very fat women the treatment could not be carried out for obvious mechanical reasons. Massage of neighbouring parts following treatment relieved the irritation which resulted from the stretching of the adhesions; and in case inflammation threatened, cold was to be applied. In many cases it was possible to get good results only by working during the menstrual period. He thought hysterorrhaphy should be used after the Brandt method had failed, and in those cases where the adhesions were veil-like. He had got good results from temporary transfixion, passing his suture through the whole abdominal wall and through the peritoneum of the fundus. Some uteri were very vascular; if hæmorrhage proved severe he packed in iodoform gauze, but small amounts of blood he left to be absorbed. He thought it important to remember that several thousand women had been cured by Brandt's method, and that without a single accident. It happened quite often that after others had failed to get relief by his method, Brandt himself had succeeded in bringing about a complete recovery.

Dr. H. C. Coe remarked that he had often been disappointed in the results of ovariotomy by finding the pain and hæmorrhage still persisting. It had proved to him that it was necessary to break up any adhesions that were present about the uterus, especially posterior adhesions which held the uterus in retroflexion. Even if hysterorrhaphy did not keep the uterus up permanently in an anterior position, it at least kept it raised until the site of the recent adhesion was healed over, so that if it fell backward again it remained freely movable. In his operations he always had an assistant to raise the uterus on two fingers while he disengaged and sutured it.

Dr. W. Gill Wylie had met with a number of cases where he had produced complete relief by curing an endometritis and subinvolution in the ordinary ways, even where there was a retroflexion with adhesions. On the other hand, he had sometimes opened the abdomen, expecting to do ovariotomy, and had found everything normal except for adhesions between the uterus and surrounding parts. He thought it was considerably easier to shorten the round ligaments inside the abdomen than to do Alexander's operation or hysterorrhaphy, while it accomplished exactly the same end. Then there would be no pocket for intestines to fall into. It was only necessary to scrape raw a section of the round ligament, and then fold and tie it together at that part. When he tied off the broad ligament in doing ovariotomy he simply included a portion of the round ligament, and so raised the uterus to its normal position.

Dr. A. P. Dudley asked, from a purely mechanical standpoint, how it could be expected that two sutures through the peritoneum of the sort that Dr. Lee and Dr. Kelly had described should retain the uterus in place in spite of the movements imparted to it by the pressure of the pelvic diaphragm and of the thoracic diaphragm during labour, defecation, or other exertions, or by the uprise of a full bladder. He thought the organ must very commonly become free in a short time, although the suture might hold it up till the adhesions had had time to heal, the circulation to become re-established, and the uterus to regain its normal weight.

Dr. Lee replied that it was the main and assured result of the operation to make the uterus freely movable, and to relieve the patient of all her distressing symptoms, whether the uterus remained fastened to the anterior abdominal wall or not, and this after all other measures had been tried without the least benefit.

Dr. A. H. Buckmaster, of Brooklyn, spoke of the value of tampooning the vagina for gradually overcoming adhesions.

Dr. Buckmaster and Dr. J. S. Hawley then continued the discussion on electricity in the treatment of extra-uterine pregnancy.

The Spirit of the Societies.

Medical Society of London (Sir William MacCormac in the chair). **Case of Paralysis of the Lower Part of Trapezius.**—Dr. Hughlings Jackson showed a girl, æt. fourteen, who exhibited a curious deformity of the shoulder (wing scapula) due to paralysis of the lower part of the trapezius muscle consequent on injury.—Dr. Beevor added that the serratus also appeared weaker than on the healthy side, but reacted to faradism. He concurred in the diagnosis as to the cause of the displacement.—Dr. Jackson, in reply, said that he was, of course, unable to say absolutely that the paralysis was due to the fall. He mentioned that this paralysis had been described by Duchenne in his "Physiology of Movement," twenty years ago, but that hitherto he had not met with such a case.

* * * *

Ophthalmological Society of the United Kingdom (J. W. Hulke, president). **Suppurating Hydatid Cyst of the Orbit.**—This case was communicated by Dr. Rockliffe. The patient, a labourer, æt. thirty-three, had first noticed an affection of the sight of the left eye in 1882. He had several attacks of inflammation in it, and the vision gradually deteriorated till April, 1887. He was quite blind with it. There was then marked protrusion, some ptosis, and the action of all the ocular muscles except the external rectus was very limited. Nothing definite was made out as to the condition of the orbit. Eighteen months later, having suffered intensely, the patient consented to an operation. An exploratory puncture with a scalpel having given no result, the orbit was more freely opened up, and the eye being removed, a suppurating hydatid cyst was found at the apex of the orbit. The rarity of the affection and the difficulty of diagnosis were briefly alluded to.—Mr. Brailey asked if there were any hydatids in other parts of the body. He thought that in Dr. Rockliffe's case the hydatid had developed in the substance of one of the ocular muscles.—The President said he had only seen three or four cases, and he thought an accurate diagnosis could not be made. In one of these cases there had been suppuration. He did not see how suppuration could be caused by rupture of a hydatid cyst.—Dr. Rockliffe, in reply, said the patient attributed the suppuration to a blow with a piece of iron. No hydatids could be found elsewhere. He thought the cyst had developed behind the eye, and had not been attached to the muscles, for the patient had free movement in every direction.

A Peculiar Form of Degeneration of Lens.—Dr. Doyne gave a brief account of a case where there was a difference in refraction of eleven dioptres between the periphery and the centre of the lens. The patient was seventy years of age, and the condition had been developing for some years.—Mr. Hartridge asked if the condition could not have been congenital.—Dr. Bremner thought that many cases were ascribed to conical cornea and astigmatism, which were really one, to irregularities in the lens.—Dr. Doyne said he did not think this case was congenital.

A Case of Recurrent Transient Blindness.—Dr. Doyne read the notes of this case. The patient had been invalided home from India after malarial fever; before his return he had a sudden attack of blindness, which completely cleared off in five minutes. Another attack came soon after his arrival in England, which did not quite pass away for more than three weeks. When he first came under notice, three days after the attack, the upper field of vision was restored. There was a dense white fog in the upper half of the fundus, completely veiling the choriod, but in which the retinal vessels stood out brilliantly. The cause of the attack seemed doubtful.

Royal Academy of Medicine in Ireland. *Surgical Section* (Edward Hamilton, president). **Peculiar Dislocation of Thumb.**—A paper was read by Mr. Dallas Pratt on lateral luxation of the ungual phalanx of the thumb, the dislocation being complete, and the direction of it upwards. He believed that the case was so rare as to be almost unique. The patient, a man about forty, slipped in the street, and putting out his hand to save himself came down on the point of his thumb. The injury was very difficult to reduce, the ordinary methods—clove hitch, Hey's knot, Levi's apparatus, etc.—having failed. Finally, by bending the joint, so as to increase the deformity and bring the phalanx at right angles to the proximal ones, and then making traction in the axis of the thumb, the bone went back into its normal position. There was no fracture, and the dislocation had not recurred a year after reduction.—Some remarks were made by Mr. Wheeler and the President, to which Mr. Pratt replied.

Cholecystotomy.—Mr. Kendal Franks read a paper on a case in which he had operated on September 10th, 1887, for the removal of gall stones. The patient, a lady, fifty-two years of age, had suffered from colic, jaundice, and severe feverish attacks, from December, 1886. After her admittance into hospital, the attacks became of almost daily occurrence. The diagnosis was rendered difficult, as she had a tumour occupying the right side from the costal arch to the crest of the ilium. A small globular tumour was felt between this and the umbilicus during

the attacks of pain. The patient was in a very exhausted condition when the operation was performed. The tumour on the right side proved to be an abnormally enlarged right lobe of the liver. The gall bladder contained four calculi, which were removed—no tumour could be found—the obstruction being due to a stricture of the common gall-duct. The woman made a good recovery.—Mr. Barton said he had a similar case a year ago to that of Mr. Franks. The patient was an elderly woman who had suffered from symptoms of gall stone for many years. She was very thin, and her nutrition had suffered from long continual disease. She was heavily jaundiced, and the abdomen on palpation showed a well-marked tumour in the region of the gall-bladder. The operation was perpendicular to the costal cartilages, about four inches in length, and the peritoneum was readily reached and opened. A number of gall stones were found in the gall-bladder, some being impacted in the common duct. The anterior wall of the bladder was stitched to the edge of the incision. The lower part—close to the gall-bladder—having been opened, a large gush of greenish-yellow bile followed, and he removed with his finger three large stones. The great difficulty was to reach the stones impacted in the duct, which constituted the cause of the obstruction. Squeezing or pressing was out of the question, and the only course was to reach the stone or stones with the finger or the forceps. Once the stone had passed through the duct, it was exceedingly difficult to reach or press it in any way so as to make it slip backwards. After manipulation he extracted another stone, and concluded that his operation had been successful; but it was not, although the wound was antiseptically dressed, and there was an excellent recovery. There was no peritonitis, except in glueing the edges together, and there was no bad result. At the same time, there was no relief to the jaundice, and the obstruction remained. The dressings were saturated with bile. She expressed herself very much relieved, and her appetite increased; but being an elderly woman she never gained strength from the low state of nutrition into which she had fallen. In the course of three months she died.

Section of Medicine (Lombe Athill, M.D., president). **Mixed Typhus and Enteric Fever.**—Dr. C. J. Nixon read a paper on a case of mixed typhus and enteric fever, and exhibited the *post-mortem* appearances of Peyer's patches.—Mr. Molony asked if there was a case of typhus in the wards, or if there was any evidence of the existence of typhus in the house from whence the patient came.—Dr. J. W. Moore said he saw, on October 17th, in consultation, an officer supposed to be at the sixth or seventh day of typhoid. The symptoms of typhoid present were tympanitis and diarrhœa, but the case was more like typhus or acute pneumonia. Next morning the patient was covered with maculated eruption, and whether he had been in typhoid previously or not it was evident he was then about the sixth day of typhus. Whatever other fever he had, there was no doubt he had maculated typhus, although the spots gradually faded, and were hardly perceptible at the time of death. There was no opportunity of making a *post-mortem* examination.—Mr. Delahoyde had had two cases in which typhoid and typhus co-existed in the same individual, and both terminated fatally.—Mr. H. G. Croly mentioned the case of a young gentleman who had had symptoms of typhoid, but afterwards the fever ran the ordinary course of typhus.

* * * *

Medico-Chirurgical Society of Edinburgh (John Cheine, M.D., F.R.C.S.E., vice-president, in the chair). **The Treatment of Diphtheria in Children by Antiseptic Steam.**—Dr. Craig read a paper in the place of Dr. F. Wyld Pairman Auckland, in which, after discussing several of the accepted methods of treatment, the author advocates strongly the use of steam. The child should live in an atmosphere of steam. This was advantageously combined with sulphurous acid through the burning of sulphur in the room. Since the author had adopted the method he had not lost a single case. Several speakers gave corroborative evidence as to the value of the method. It was generally admitted, however, that the system was not new, as with many practitioners it had been for years routine practice.

* * * *

Royal Medical and Chirurgical Society (Sir H. Sieveking, M.D., president). **Eighty Cases of Chorea. Antecedents, Family History, State of the Heart, and Subsequent History.**—The above paper was read by Dr. P. Herringham. We give a summary. *Antecedents:* Acute rheumatism preceded the attack in nineteen cases, immediately in four; at some intervals in fifteen. It accompanied the chorea in two cases. Pains in the joints accompanied the chorea in two cases, and preceded it in fifteen. The total number of cases in which rheumatism could be traced was thirty-seven. Injury, shock, or violent bursts of emotion in six cases. The interval was never greater than two days. Hard mental work or worry was found in twenty cases. In twenty-five cases none of them could be traced, and of these fourteen were first attacked. Nearly all the patients were delicate; headache and indigestion were the most common complaints. *Family History* (calculated from parents, brothers and sisters only): Rheumatic fever had occurred in twenty-five out of seventy-five families. Seventeen of which belonged to thirty-four patients of the rheumatic classes, and the remaining eight to forty-one in whom there was no history of rheumatism. Chorea had occurred in twelve families, nine of which were rheumatic. *State of the Heart Throughout:* Natural in ten, uncertain endocarditis in twenty-five, and certainly diseased in twenty. Signs of disease developed during observation in eleven cases, and signs which were at first present vanished in four during observation. The following conclusions were drawn:—1. That a large number of choreic patients were liable to rheumatism. 2. That choreic patients were nearly always of a delicate constitution. 3. That chorea was sometimes directly caused by emotions. 4. That chorea might cause permanent heart disease. 5. That it also gave rise to signs of heart disease which were not permanent.

* * * *

British Gynæcological Society (Arthur Edis, M.D., president). **Pyosalpinx.**—Mr. Lawson Tait showed the appendages which he had removed from a lady æt. thirty-nine. She had married at the age of seventeen, and had two children within twenty months of her marriage. Soon after her confinement she contracted gonorrhœa from her husband, and she had never known what it was to be well since. She had led a life of simple misery for several years. Then she married again, but never became pregnant by her second husband, so that ever since she has been nineteen or twenty she has been absolutely sterile. She had double pyosalpinx of old standing, and it was very difficult to say which was tube and which was ovary. There were abscesses in both ovaries, and if he had attempted to tap them from the vagina he would have been obliged to tap several cavities. The patient was now practically cured.

Removal of Uterine Appendages.—Dr. Savage exhibited appendages, which he had removed from two women, aged about twenty. In one case pus was found in one ovary and one tube; in the other case small cysts were found in both ovaries, the right one being the size of a pigeon's egg. In both cases there had been pain for a long period, and they had been under treatment two or three years previously without benefit.—Dr. Routh said he had seen many cases in which an abscess having formed in the ovary, the contents had become indurated from absorption of its liquid portions, and there had been no further annoyance. He thought that in many cases it would be sufficient to puncture through the vagina and inject iodine, etc.—Mr. Lawson Tait said that a man who would neglect his obvious duty in such a case for the sake of a hypothetical future baby would be neither more or less than a criminal. He denied that tapping ever effected a cure. Even a simple parovarian cyst would refill and require removal, and an abscess of the least, which was easily accessible, could not be cured by such means.

* * * *

Glasgow Southern Medical Society, Thursday, January 10th (John Glaister, M.D., in the chair). **Radical Cure of Hernia by Dr. Macewen's Method.**—Dr. S. G. Campbell exhibited and described two cases in which this operation had been performed by Professor James Dunlop in the Royal Infirmary. The one patient was a boy, with congenital inguinal hernia; the other, a man of middle age, with a large scrotal hernia. The former had undergone operation by another method, which failed owing to whooping-cough, the gold wire requiring to be removed. On that account the cicatrix in the groin was longer in extent than usual.

* * * *

Glasgow University Societies, Friday, January 11th. **Conjoint Discussion on Cremation.**—The Dialectic, Medico-Chirurgical, and Theological Societies met together to discuss the subject of cremation. Mr. Farquharson, treasurer of the Medico-Chirurgical, declared in favour of cremation, and from the medical point of view not only made out his case in favour of the new system, but incidentally pointed out the increasing dangers attendant upon the present burial system.—A very complete and able reply was then tendered by Mr. F. G. M'Killop, a member of the Dialectic, in which he made light of some of the alarmist opinions of the doctors, and laid special stress upon the case with which justice might be baulked where murder had been committed by poisoning.—The doubtful factor in the minds of many lay with the Theological Society, but their fears or hopes were set at rest when a member of the society gave cremation his support in an effective little speech. The discussion throughout was lively, and at times humorous to the verge of ridiculousness. At the close there voted for the affirmative, sixty-three; and for the negative, seven.

Glasgow Medico-Chirurgical Society, Friday, January 18th (Professor McCall Anderson, M.D., in the chair).—**The Pulmonary Vesicular Sound.**—Dr. D. C. McVail explained his theory that this sound was produced by "flutter resonance" in the pulmonary vesicles. Air passing over a sharp edge in entering a cavity was thrown into flutters. As in an organ pipe one of these flutters would assume the dignity of a musical sound. So air entering into infundibula of the lung, struck against the edges formed by the septa of the vesicles, and was thrown into flutter. The theory of "fluid vein" would not hold as applied to the production of the sound in the pulmonary vesicle, for that theory required two conditions which were not both present in the lung—namely, the entrance of a stream of air, and resistance to that stream. The latter condition was not present in the air vesicles, because they yielded before the current of the air, and underwent enlargement. There was a small period of minus tension, for the air was drawn in by the walls of the vesicles making way. The inspiratory part of the sound he held to be vesicular and not due to "fluid vein," but to "flutter resonance." The respiratory sound in incipient phthisis was not vesicular in its origin, but was produced in the bronchial tubes. A tubular murmur was heard in pneumonia and the vesicular sound was absent, because the pulmonary air vesicles were filled. The lung tissues was thereby made a better conductor of sound, and so the tubular sound was obtained. In incipient phthisis the pulmonary sound assumed a wavy character, the wave being synchronous with the heart beat. Afterwards the respiration became "cogwheeled" in character, and finally the heart beat itself was heard in the lung. Dr. McVail held that intravascular murmurs were wholly due to "fluid vein;" but that theory could not explain the pulmonary sound in the air vesicles.—Dr. George S. Middleton did not think that sound entering the air vesicles could produce an audible sound, or a musical note. The septa of the air vesicles did not form such definite edges as shown by Dr. McVail. He considered that wavy murmurs were sometimes caused by the heart's action, but not always.—Drs. Dunn, Wallace Anderson, and the Chairman made some furthers remarks, and Dr. McVail in his reply contended for his theory of the origin of the pulmonary vesicular murmur in the vesicles themselves as against the old theory of its origin in the trachea. If a portion of the lung did not expand, the entering air produced "fluid vein" if the resistance was sufficient. The "resonance flutter" swallowed up the "fluid vein," but sometimes the latter contributed to the production of the vesicular murmur.

* * * *

Liverpool Medical Institution, December 6th (Dr. Carter, president, in the chair).—Dr. Karl Grossman read a paper on **Hypnotism.**—He said that he was first led to investigate the subject by the experience of a friend, in whose judgment he had firm faith. He then went to Paris and attended M. Charcot's demonstrations at the Salpétrière. M. Charcot distinguishes three stages of the hypnotic state. 1. That of lethargy, produced by fixing the eyes with a bright point, or by compression of the eyelids. 2. That of catalepsy, produced by lifting the eyelids of the subject while in the first stage; or directly by a sudden shock to the sensory nerves, as by a flash of light. In this stage every muscle retains the position in which it is placed, like a painter's lay figure. 3. That of somnambulism is produced by gently rubbing the vertex in either of the foregoing stages. Charcot also states that some people have certain zones, the stimulation of which will produce lethargy. Dr. Grossman saw all these different stages demonstrated at the Salpétrière, but was not able to get any explanation of them. From Paris he went to Nancy, when he saw Drs. Liébault and Bernheim. They differed from M. Charcot in their method of procuring sleep; they doing so by suggestion only. Dr. Liébault believes that the hypnotic sleep differs from ordinary sleep, in that there exists a relation between the sleeper and the operator; whereas in ordinary sleep the sleeper is wrapped up in himself. Liébault suggested sleep by placing the patient in a comfortable chair, and talking quietly to him. The Nancy School differs from that of Charcot in that they do not recognise the three stages of lethargy, catalepsy, and somnambulism, but produce any of these conditions directly by suggestion. Bernheim demonstrated that the suggested effect existed only in the idea of the subject. For example, it was suggested that he could not see a certain thing in the room; he then acted just as if he were unable to see the object, although it was plainly visible to others. Dr. Grossman also spoke of remarkable vaso-motor effects produced by suggestion, such as a blister, when a postage stamp was applied, and the patient was told that vesication would take place. Dr. Grossman thought that the principal field for hypnotism would be among nervous disorders; although not necessarily among hysterical patients. After the paper Dr. Grossman demonstrated many of the above facts on two subjects whom he hypnotised by suggestion.

Clinical Society of Manchester, January 10th, 1889 (Dr. Simpson in the chair). **Compound Dislocation of the Ankle.**—Dr. J. Eames showed a patient who had recovered from compound dislocation of the ankle with perfect movement, and attributed the excellent result to the thorough manner in which the joint at the time of injury had been irrigated with corrosive sublimate solution, 1 in 1,000. A drainage-tube and antiseptic dressings were used. The pulse and temperature never exceeded 100. In three months the patient was able to walk five or six miles, and was free from lameness.

Enlarged Spleen with Anæmia.—Dr. Owen showed a case of enlarged spleen with anæmia in a child which had been under observation for above three years. The child, a boy, was five years of age when he was first brought to the hospital. Shortly after the first visit paralysis of the soft palate occurred, with nasal utterence and rejection of liquid food through the nose. The tonsils were enlarged, and also the upper cervical glands. The whole of the symptoms were considered to be the result of an attack of diphtheria. The spleen continued to enlarge, until it reached the level of the umbilicus. Slight dilatation of the left ventricle of the heart occurred during the progress of the case, and a systolic apex murmur had been noted, with marked accentuation of the pulmonary second sound. This murmur was audible only in the recumbent posture, a peculiarity which Dr. Owen had frequently observed in conditions of anæmia and debility. He attributed it to a relative incompetence of the mitral valve, which the lessened energy of contraction of the ventricle in this posture rendered apparent in a weakened heart. The condition of splenic anæmia, he thought, was not infrequent in children, and that it was for the most part due to disturbance of the blood-forming process brought about by a great variety of diseases. In this case great improvement had taken place under the prolonged administration of iron and arsenic.

Hydronephrotic Kidney.—Mr. Stanmore Bishop showed a patient from whom he had removed a hydronephrotic kidney twelve months since. The wound healed rapidly with the exception of a small sinus leading down to the ligatures, which were of Chinese twist. After waiting six months Mr. Bishop cut down upon the urethral ligature and removed it. It was found unchanged. The sinus still persisted, but last month it finally closed. The urine now passed was of sp. gr. 1,022, and contained no albumen, casts, or crystals, and was of normal quantity. No signs of renal insufficiency had shown themselves at any time. The case was originally reported in the *Lancet*, May, 1888.

Hydatid Tumour of the Liver.—Dr. Railton showed a girl, æt. fourteen, with an hydatid tumour the size of a cricket ball, placed in the middle line in the epigastrium. There was no thrill obtainable. It had been observed for the last four or five months, but had given rise to no pain or other disturbance. Dr. Railton had drawn out with a small subcutaneous syringe, a small quantity of the hydatid fluid a fortnight previously, and the tumour had already apparently began to shrink.

Disseminated Sclerosis.—Dr. Railton showed a little girl, æt. nine, suffering from disseminated sclerosis which had an usual mode of onset. She was born naturally, cut her teeth in good time, and had never suffered from convulsions. She did not walk until three years old, and it was then observed that her gait was as awkward as at present, somewhat spastic, the knees and toes turned inwards, and a slight overlopping of the legs during progression. The hands had the characteristic large tremor, greatly increased upon attempting to do anything requiring the least exactitude, such as the conveying of a glass of water to the lips. The legs when hanging down without support were perpetually in motion, with jerkings very like the irregular movements of chorea. All movements ceased entirely on the limbs being allowed to rest. Although weak and uncertain upon her legs, she was able to stand with her eyes shut. A peculiar expression of face perceptible, and a tendency to cry and to laugh unreasonably had been noticed in the wards. Her speech was syllabic, drawling, monotonous, and weak, dying at times at the end of a word. The knee jerk was present but restrained by spasm. There was no mystagmus nor vertigo: sensation appeared perfect and the faradic reactions were everywhere normal. The muscular sense seemed to be slightly impaired. The bladder and rectum were unaffected. No family history of neurotic disease elicited, and there were five other perfectly healthy children of the same parents. It was evident that the etiology of such a case was wrapped in impenetrable obscurity.

* * * *

Pathological Society of Manchester, Wednesday, January 16th, 1889 (A. H. Young, M.B., president, in the chair).—**Thrombus of the Retinal Veins.**—Dr. Mules showed drawings of primary retinal phlebitis, where clots were seen in the vessels, entirely blocking up some of the larger veins.

Enlarged Spleen Removed by Operation.—Mr. WRIGHT and Mr. THORBURN showed the specimen, with sections, of a spleen removed from a man of thirty-five for hypertrophy, with severe accompanying pain. The details of the case have been already published (*Medical Chronicle*, December, 1888). The sections showed slight thickening of the capsule, a condition frequently seen in hypertrophy, the thickening being more marked when the organ lay in contact with the chest wall. There was slight—but only slight—increase in the fibrous stroma. The arteries had mostly thickened walls, some being almost obliterated by endarteritis. The veins were dilated. The splenic pulp itself was practically normal, although in excessive quantity. The malpighian bodies were well marked, and there were a few cells with double nuclei, and still fewer giant cells. Practically, therefore, this was a case of simple hypertrophy arising without any obvious cause. This affection is but briefly referred to in most of the works on general medicine and pathology, but the brightest record of collected surgical cases would appear to show that it is not very uncommon.

Intussusception of the Small Intestine.—Dr. YATES showed a specimen of the intussusception of the jejunum which was taken from a child two years old, who was admitted to the wards of the Bolton Infirmary, under the care of Dr. Mallett, on November 9th, 1888, suffering from extensive burns of the third degree over both arms and abdomen. The child progressed favourably until November 24th, all the sloughs having come away, leaving healthy granulating surfaces, when persistent vomiting set in. There was slight tenderness in the epigastrium on deep palpation, but no tumour could be detected. The vomiting continued, and the child gradually got weaker, dying on the 27th. Duodenal ulcer was diagnosed at the time, and was accordingly treated. At the *post-mortem* the intussusception was found, the duodenum being perfectly healthy, as also were the other viscera. There was slight congestion of the intussuscepted portion of the gut, but the obstruction was not complete, allowing the passage of a goose quill. The case was one of interest, inasmuch as the symptoms came on during the third week of an extensive burn, and simulated those of duodenal ulcer.

* * * *

CLINICAL SOCIETY OF LONDON (W. H. Broadbent, M.D., F.R.C.P., president). **Sequel of a Case of Epithelioma of the Vocal Cords, for which Partial Excision of the Larynx was Performed.**—Mr. Butlin read particulars of this case. Recurrence of the growth took place about nine or ten months after the operation of partial excision. Tracheotomy was performed exactly one year after the first operation. The patient survived the operation of tracheotomy one year and two months, when he died slowly of exhaustion.

Disease of the Larynx.—Mr. BUTLIN also sends notes of the cases. In pursuance of an opinion expressed by him in a previous paper, that it is necessary to remove the cartilaginous, or bony framework of the larynx in certain case of intrinsic carcinoma of the larynx which are suitable for operation, two cases were reported. He also gave another instance of a case in which he performed an exploratory thyrotomy in a man advanced in years, and found the disease too extensive for removal; he closed the wound, and the man recovered and left the hospital, wearing a tracheotomy tube.

* * * *

BRADFORD MEDICO-CHIRURGICAL SOCIETY (H. C. Major, M.D., president). **Arrested Growth of Radius.**—Mr. HORROCKS read a paper for Mr. J. Appleyard on a case of arrested growth of lower epiphysis of radius (child shown) after a fall of eleven months previously. The lower epiphysis of the vena and radius were connected with the bone above by fibroid tissue.

Laparotomy for Ovaritis.—Dr. A. RABAGLIATI read notes of two cases of laparotomy for ovaritis. One of the cases, the first fatal case of laparotomy for oöphorectomy under Dr. Rabagliati's hands, died on the fifth day. The ovaries had been partly adherent owing to inflammatory changes subsequent to a miscarriage, and there was constriction of a piece of small intestine by an adhesive band. The second patient recovered, and was relieved. In both cases hydrastis canadensis had been tried previously, without any result.—In the discussion, Mr. VAUGHAN dwelt on the good effects he had seen from the use of nitroglycerine in ovarian dysmenorrhœa.

Chrysarobin in Psoriasis.—Dr. MAJOR read notes on the use of chrysarobin in psoriasis by the Auspitz method (painting the eruption with chrysarobin dissolved in liquid guttapercha), commenting on the cleanness and efficacy of the method.

OBSTETRICAL SOCIETY OF PHILADELPHIA. **Pyosalpinx.**—Dr. L. J. HAMMOND reported a case of pyosalpinx. N. J——, æt. twenty-two years. Had one child three years ago. Since that time she has not felt well, having frequent attacks of pain in the pelvic region, confining her to bed for weeks at a time. About nine months ago she had a hæmorrhage from the uterus lasting three weeks, followed by a purulent discharge with severe pain and great tenderness of the abdomen, especially low down, necessitating her remaining in bed two weeks. After this time she resumed her occupation, that of a laundress, until four weeks ago, when the pain became so intense she was again obliged to go to bed, where she remained one week without attendance. At this time I found her with a temperature of 100°, pulse of 120, abdomen tympanitic and so very tender she could not bear the weight of my hand upon it, together with menorrhagia. Digital examination was deferred until the next day, owing to the great distention of the bowels with fæces, which naturally increased the pain. Upon examination per vagina, I found a uterus very much enlarged, and bound down firmly posteriorly, together with a large boggy mass on the right side, which was very sensitive to touch. An immediate operation was advised, but was delayed, owing to the absence of relations, until October 18th, when with the assistance of Dr. J. M. Baldy, the abdominal cavity was opened, and a large abscess with pyosalpinx was removed from the right side, with great difficulty, owing to extensive adhesions. Several small pus pockets were ruptured during the removal, and about an ounce of pus was discharged. The left ovary was not removed, it being apparently healthy. After thorough irrigation a glass drainage-tube was inserted, and was replaced on the fourth day by a rubber one, which removed in twenty-six hours. It is to-day just two weeks since the operation, and the patient is well. At no time did the temperature rise above 99½.

Dr. J. M. BALDY said that it had been stated in the society by a member that he had never seen pus in a tube primarily. The specimen presented was interesting in that connection, as there has been pus in the tube as a primary condition. There was not pus present then as the specimen had been cut open, and had been for a long time in alcohol. There were two sacs in the ovary, one contained pus, and the other a blood clot as large as a walnut.

Dr. PRICE, in answer to a question, whether the matter contained in these abscesses was really pus or not, said there could be no question but that it was pus. He was quite sure that it had been examined under the microscope.

Dr. B. F. BAER thought that he was the culprit referred to by Dr. Baldy. In the discussion of this subject before the Society, last winter, he was reported as having made the above statement, but he had been misunderstood. What he really did say was, that in his experience primary pyosalpnix was a rare disease; that in the uterine appendages which he had removed, the condition was an inflammatory one, involving the tubes, ovaries and pelvic peritoneum, which had resulted in glueing or matting together the organs, but that he had failed to find pus contained in the tubes and nowhere else; that in the pus cases with which he met, there was a condition of abscess in which it was difficult to tell whether the disease had originated in the tube, in the peritoneum or in the cellular tissue, so extensive was the distruction of the tissues and organs in these cases. It would be a very sweeping statement to say that primary pyosalpinx never occurred, and he did not wish to be misunderstood as making it. His experience during the past year confirms the views which he then expressed.

Dr. HAMMOND said there was no question about there being pus in this tube. The tube was larger than his thumb, and thoroughly distended with pus.

Double Intraligamentary Cysts.—Dr. WM. GOODELL gave the the history of a case of double intraligamentary cysts. The woman, æt. 30 years, had been infected with syphilis from which she had suffered with constitutional symptoms. Two tumours had been discovered a year ago. Her health had failed rapidly and œdema of the upper and lower extremities were present. The womb was so closely adherent to the tumours and they were so immovable, that a diagnosis of one multilocular intraligamentary cyst was made.

Dr. GOODELL also shewed the *left ovary* of a young girl, 22 years old, which he had removed, and which had *two pus cavities* in it. The girl in this case was a virgin, and he felt very confident that gonorrhœal infection could be excluded. Owing to a constant oozing of blood the drainage tube was kept in for eleven days, a rubber one being substituted for the glass one at the end of the first week. Not any complications have retarded her convalescence.

Intraligamentous Cyst.—Dr. B. C. HIRST showed an intraligamentous cyst. This specimen was recently removed by an operation

performed by Dr. T. H. Bradford, at which I had the pleasure of assisting. The tumour sprang from the right broad ligament and was attached deep down in the pelvis. Its blood-vessels were enormous. It was covered by that curious muscular-looking capsule which makes these tumours resemble an enlarged uterus. There was furious hæmorrhage at the lower attachment when an attempt was made to ligate the pedicle. This was easily controlled by a long pair of catch forceps passed in the dark. The entire tumour was removed, and the stump cauterized. The operation lasted three hours, and the woman almost died on the table. She recovered from the immediate effects of the operation, but died three days later. The mass consists of a papillary growth internally, and a capsule which shows features referred to by Dr. Goodell in a meeting of the society last December, and that is the seeming rottenness of the tumour wall in spots, which makes it exceedingly difficult to remove these growths without tearing them and allowing some of their contents to escape into the peritoneal cavity. This happened in the present case. Had the woman lived it is probable that the peritoneal surface would have been infected by this papillomatous matter.

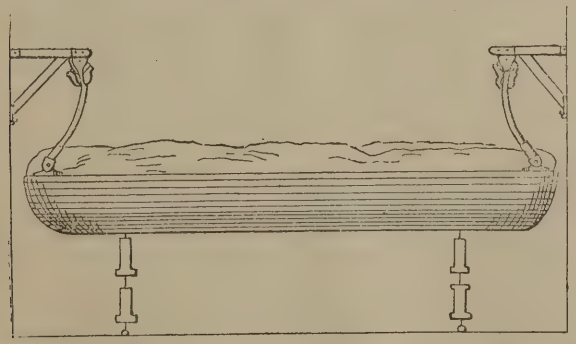
Dr. R. P. Harris gave the case of the late Dr. Emeline Cleveland, who had become infected from an ovariotomy, and had a syphilitic sore developed on her wrist, which ultimately was the cause of her death.

Dr. Joseph Price said the case reported by Dr. Goodell illustrated beautifully the primary and the secondary value of the tube; the signal of hæmorrhage and the cure of the abscess which formed later. The woman would have perished from the hæmorrhage or the abscess had the tube not been used. In regard to the virulence of living pus, he might say that he had twice been poisoned in abdominal work. Virchow had called attention, long since, to the virulence of living pus. He differed entirely from Dr. Baer as regarded the nature of the cyst which he had presented. It was clearly a parovarian cyst. It belonged to that class of tumours to which we applied the minor methods of treatment without knowing exactly what the tumour was. In this case you may strip off the capsule and still have a cyst. This could have been done more readily if the specimen were a recent one. The other day, he removed an enormous parovarian cyst, and in a few minutes was able to convert it into two cysts. Such tumours are always parovarian and the enucleation is easy.

Surgical Aids and Appliances.

117.—SWINGING BERTH FOR SHIPS.

Mr. Godwin, of Lynn, Massachusetts, U.S.A., has devised a new form of berths for ships, to prevent sea sickness. The real invention is a sort of swing for supporting a ship's berth, and maintaining it in a level position, however much the vessel may pitch or roll. It is an adaptation of the rotary movement of the ball and socket joint to a sort of wooden hammock. Brackets are screwed into the walls of the cabin, provided at their outwardly projecting ends with lugs, to which are secured the base piece of a ball-and-socket joint. A spindle, passing through the ball, supports a beam provided in the centre with an aperture into which the lower end of the joint passes. The berth is suspended to these beams at all four corners, and works easily and noiselessly. The invention has also been tested with great success on



one of the Allan Line steamers from Liverpool to America, when even the "roaring forties" were found to have no unpleasant effect upon its fortunate occupant. It has also been tried on some of the vessels of the London, Chatham, and Dover Railway between Calais and Dover, with equal success. It will doubtless be quickly introduced into other ships, especially of those great lines whose principal aim in life seems to be to seek opportunities for making a sea voyage a matter of luxury, and whose ships every year bring over and carry back so many thousands of cousins from across the herring-pond. The berth is on view at the offices of Messrs. F. Prince and Co., 31, Craven-street, Strand, London.

Medical Miscellanea.

The subject of our next illustration will be Dr. Robert Barnes.

* * * *

Dr. John R. Fitzgerald, Appelby Hitchen, Herts., has been awarded a Government grant for successful vaccination.

* * * *

Messrs. Cassell & Co. are the publishers of Letts and Co.'s medical ledger and medical diaries.

* * * *

Cassells' "Year Book of Treatment" becomes more valuable each year. The volume for 1889 is the best yet issued.

* * * *

The executive Committee of the General Medical Council will meet on Monday, February 25th.

* * * *

The Mayor of Hastings is asking for the co-operation of the residents and tradesmen in connection with the Health Congress, over which Dr. Richardson will preside. It will be held in May.

* * * *

Dr. Joseph Wiglesworth has been appointed Superintendent of the Rainhill Asylum, to which he has for some years been Assistant Medical Officer.

* * * *

The next triennial award of the Astley Cooper Prize (£300) will be made in 1892. The subject set is "The Influence of Micro-organisms in Inflammation.

* * * *

Mr. Whitworth, Public Vaccinator of the St. Agnes District of the Truro Union, has been awarded the Government Grant for efficient vaccination.

* * * *

Mr. John Buckenham, L.R.C.P. Edin., M.R.C.S. Eng., Public Vaccinator to the borough of Cambridge, has been again awarded the Government Grant for successful vaccination.

* * * *

Dr. M. Cursham Corner, of Mile End, has been presented with a valuable bag of obstetric instruments by members of the committee of the Lying-in Home, Shadwell, in recognition of services rendered to the patients of that home.

* * * *

The candidates for certificates at a recent examination, held in connection with the S. John Ambulance Association, in Cardiff, included thirty men employed at the Bute Docks, sixteen being policemen. The class had been prepared by Dr. Wallace. Dr. Thomas, Bridgend, complimented the men upon the proficiency shown.

* * * *

A case of poisoning by false teeth is reported from New Haven. The sufferer recently bought a set of false teeth with a rubber plate. He had worn them but a short time, when his tongue began to swell. His eyelids also swelled up so that he was blind for a time; other parts of his body became similarly affected.

* * * *

The medical classes in Owen's College for the Lent term were re-opened on January 9th. Dr. Henry Simpson, who has been connected with the Royal Infirmary of Manchester for many years as Physician, has resigned that office. Dr. Graham Steel, Assistant Physician, receives the appointment of full Physician.

* * * *

The Royal Academy of Sciences, Turin, announces that the new term for the seventh Bressa Prize has begun. The prize is of the value of 12,000 Italian lire, will be given to the scientific author or inventor (whatever his nationality) who during the years 1887 and 1890, shall have made the most important and useful discovery, or published the most valuable work on physical and experimental science, natural history, mathematics, chemistry, physiology, or pathology, as well as geology, history, geography and statistics. The term will close at the end of December, 1890.

J. Walker Downie, M.B., F.F.P. and S.G., has been appointed Surgeon to the Department for Diseases of Throat and Nose, in the Glasgow Western Infirmary, *vice* John Alexander, M.D., resigned.

* * * *

Medical men who smoke will be glad to know of a good pipe. It is the Fumo-per-purgans of Bennett. The name is not a happy one, but that does not take away from the value of a pipe which smokes cool, and is permanently clean.

* * * *

Pepsin has been recommend as a surgical dressing by Dr. Henry B. Douglas, New York, either dusted or applied in ointment. In ulcerations covered with a slough, or having a membranous base, it leaves a healthy granulating surface.

* * * *

Two medical men have recently been sentenced in France to four years' imprisonment, 1,000 francs compensation, and five years of interdiction of cure and political rights for making a medico-legal report imputing criminal abortion on insufficient data. The report appears to have been made in good faith, but they relied upon statements obtained outside the *post-mortem* room, and their medico-legal report was influenced by this information. The punishment inflicted is of course severe, and shows how strict French laws are. We believe there can be no doubt that the woman did die of abortion, but there was no scientific proof from the *post-mortem* that the abortion was caused artificially.

* * * *

"Do you know there are eleven and a half tons of postage stamps sold at the New York post office every year?" asked a manufacturing chemist of a reporter the other morning. "Now, guess how many tons of pills are made in this country every year." "What have postage stamps to do with pills?" said the reporter. "Nothing whatever, save that each is useful in its way. I only cited the post office vend to give you an idea of the great weight of small things when considered in bulk. Give it up? Well, as near as can be figured they will amount to over fifty-two tons a year. A ton a week is a fair estimate. In England alone there are two billions consumed every year; that, reduced to tons, would make about forty. How many are used in other countries it would be hard to say, but the total would not come far from 450 tons. Say, 500 tons are used a year by the entire world. The habit of pill-taking is ancient. It is the most convenient form of taking medicine, and is the most popular. Formerly, they were made by the hand; now they are produced by machinery. There are a few manufacturers who make a million pills a week." Messrs. John Richardson and Co. turned out last week 6,213 gross, or 894,672 pills.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, Friar Lane, Leicester.

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16th of the month.

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

SACCHARIN.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

DEAR SIR,—We notice in the January number a leaderette headed the "Saccharin Controversy," in which the imputation of motive is justly deprecated, and the assertion made that "the objection to this agent in France arose from a desire to protect native industries—a conclusion hardly warranted by the facts." Now as a matter of common knowledge, the objection to saccharin in France *did* arise from the desire you mention, and we are going to try to prove to you out of the *ipsissima verba* of the chief actors in this "Saccharin Controversy" that this *was* the case, and that such a conclusion is perfectly justifiable. No one can more thoroughly deprecate the imputation of interested motives than we ourselves do; and in the pamphlet which we recently published, entitled "A Vindication of Saccharin," we were very careful to emphasize our ideas on this point, but facts are very stubborn things, and when words are taken down as uttered and reported in the authorised publication of the Society to whom they are addressed, it may be taken that they authoritatively represent the opinions and motives of the speaker, and we think we shall be able to show you out of the mouths of the prime movers of the opposition to saccharin in France, that it was rather a question of protection by which they were actuated rather than by any zeal for either science or hygiene.

Dr. Worms started the discussion, so we will take his case first. It cannot be said that he is a great medical authority whose dictum would weigh against that of men of such standing as Drs. Pavey or Thomas Stevenson, to say nothing of his own compatriots, Drs. Constantin Paul or Pietra Santa. Dr. Worms reads a paper before the Academy of Medicine of France—a body before which one would think only a purely scientific paper would be read, but this particular composition bristled with considerations purely business-like, from which we cull the following as samples of the bulk:—"If we succeed in dethroning beet sugar by the substitution of saccharin in alimentation in any form, the universal sugar industry would be greatly disturbed. . . . If some less costly process of manufacturing saccharin is discovered, it is without the shadow of a doubt that the competition of sugar would be difficult. . . . The principal point which dominates the whole question is that the substitution of tar sugar for cane or beet sugar is a matter of certainty; the day the cost of its manufacture becomes sensibly lessened." He then entered into an elaborate calculation to prove that even at its present price, saccharin in terms of relative sweetening power was less costly in France than beet sugar. Surely here be motives. After such eminently commercial arguments as these, he cited four cases, in three of which he alleged saccharin had disagreed with the patients, causing digestive troubles. These cases were of such a flimsy nature that unless further evidence could be procured, it was certain that the sense of the Academy would be against placing any reliance on his experiences. He therefore came to London to see Dr. Pavy, who told him that he had never found its use to cause dyspeptic troubles, but he had found patients take it with great satisfaction. On his return to Paris Dr. Worms informs the Academy that "Dr. Pavy, like himself, had found saccharin to cause digestive troubles, so much so that he had quite discontinued its prescription." When Dr. Pavy wrote and requested him to contradict this statement, "which was diametrically opposed to the words he did say," what did Dr. Worms do? He merely stated before the Academy that Dr. Pavy wished him to state the nature of the dyspeptic troubles he had observed from the use of saccharin, and in deference to that request he begged to state that it was a prolonged and sweet taste in the mouth. Your article says the Pavy-Worms controversy arose from a mistake. Personally we should have used a much stronger word.

The next opponent of saccharin is Dr. Dujardin-Beaumetz, who is a man of much greater eminence than Dr. Worms. Shortly before the date of Dr. Worms' paper Dr. Beaumetz read a paper before the Therapeutical Society of Paris, in which he said: "I do not know how too forcibly to recommend to you the use of saccharin, which permits of the use of dishes of a most agreeable flavour, quite equal to those made from sugar." Taking part in the discussion on Dr. Worms' paper, Dr. Beaumetz said he certainly had never observed in the many cases where he had used saccharin any of the troubles spoken of by Dr. Worms; on the contrary, he cited instances in support of an opposite view; but he says, "if, as our colleague has forcibly said, saccharin is to compete with the sugar industries, the question assumes another aspect, and its sweetening power makes it a dangerous rival to sugar, whilst already it is largely used in the industries."

To the foregoing remarks let us adduce the message of M. Lepére, Secretary-General to the Prefecture of Police, who in appointing the committee, of which that turncoat, Dr. Dujardin-Beaumetz, was president and reporter, said: "The use of this new product threatens the interests of the Treasury, of agriculture, and of the sugar industries. It is also possible that it may injure the public health." Is it not apparent that the last sentence was an indication of the loophole by which the committee were to escape any criticism on their report? Surely these words show distinct motive, and in face of them whereof it needs no Œdipus to read between the lines; if interested motives have been imputed, the imputation is thoroughly deserved and justifiable. As a matter of fact, the first people to point out the object of the opposition were the French papers, *La France*, *La Patriote*, and *le Courrier*

de Lyons, but really the underlying motive was too apparent to escape notice. It is well known that France is distinctly a protectionist nation, and saccharin is not the first article of universal commerce they have interdicted. It is impossible to import lucifer matches and velveteens into that republic (!) to say nothing of pork and salicylic acid; whilst the tobacco trade is in the hands of a regie, who work it as an absolute Government monopoly.

In contradistinction to the action of the French Government (which is the only country where any one has raised a voice to dare assert that saccharin is in any way toxic or harmful to health) we have the Governments of Holland, Italy, Belgium, and Austro-Hungary. who have all declared officially, after consultation with their respective academies of medicine, that there is nothing harmful in saccharin which should cause any regulation of its importation, which is permitted, as also its use in articles of food.

As to the question raised in France as to the noxious effect of saccharin on the system, we have only to point to the foregoing paragraph, and to the opinions to the contrary of the highest authorities in France itself, England, Italy, Germany, Switzerland, and Belgium (which we print in our "Vindication of Saccharin") to show the utter hollowness and absurdity of any such theory.—Apologising for the extreme length of our letter,—We are, dear Sir, yours truly,

WILSON, SALAMON & Co.

LIVERPOOL HOSPITAL SUNDAY AND OUR MEDICAL CHARITIES.

To the Editor of The Provincial Medical Journal.

Sir,—Now that the public are invited to give to the above, may I be allowed to call attention to some points in connection with the working of our charities. The last Charity Organisation Report stated that there has been a falling off of £3,410 in the annual subscriptions to fourteen of our local charities. Our hospitals—in so far as they confine themselves to ministering to the wants of the sick poor—are doing a noble work; but at present they are causing a great evil. It is always to be recognised that charity, at its very best, is a thing of temporary benefit only, and that when aid is permanently demanded by a family, and is given, it becomes a source of evil. It may be said that next to our Poor-law system the medical profession is the greatest pauperising body in the United Kingdom. It does more charitable work than any other. Unfortunately for the thrift of the country, the being on the staff of a charity is the chief way by which medical men advertise. I only mention this to show that we need expect little reform from those practitioners who are on the medical staff. All grant that the Poor-law is greatly abused, and that other charitable institutions are liable to be cheated, yet few or none would state that our local medical charities suffer in this respect, when a medical man will spend from £200 to £300 canvassing for an hospital appointment, his aims are likely to be other than merely posing as the minister to "suffering humanity." One London doctor has stated that it would pay a medical man to give people money so as to bribe them to come to the hospital.

Our hospital authorities do not seem inclined to check well-known abuses, with one or two honourable exceptions, they systematically repeat, "there is no abuse." It has been stated that they fear to face a public inquiry, as the condition of affairs shown, would put a quick check on the givings by snbscribers. I do not think it would. That a strict investigation is urgently needed, may be noted by the fact that out of a population of 600,000, 256,000 receive medical relief at the hospitals, and that 43,204 are provided with doctors and medicines by our three parochial authorities; nor do these numbers include those who are treated at the three city fever hospitals, or through private sources. The fact that of every three people in Liverpool, one receives medical charity is surely sufficient to bring the above serious condition of affairs to the front, and for a time at least "to give us pause." These figures compare favourably with those of other cities, for in some of these one in two goes to the hospital. The fact that when Manchester took this question up, and found that 42.32 per cent. who applied were ineligible for treatment, and that last year only 13 per cent. who applied were so, proves the wide spread abuse. And the fact that the London Hospital in Whitechapel, found that nearly 50 per cent. were not suitable cases proves it also. The reason of Liverpool demanding so much charity is explained by some that the people are poor, and in irregular employment.

But who will state that the Whitechapel dwellers are better off than the working classes here. Besides the average rate of abuse in this city is no greater than in any other towns, although the contrary has been stated. Supposing the plan followed by the Children's Hospital, London, of giving advice once only until the applicant produces a letter from the Charity Organization Society, stating that the person is worthy of relief, were put into force here, would enormous abuses not be detected. Is it not well known to a great many that people can afford to pay 5/- or 10/- for a railway ticket, and then go to the hospital for free advice; and also that many with their 12/- to 24/- per week "sick pay" take advantage of the charities. The mere fact that some medical men contract to give treatment and medicine to each member of a tontine for the sum of 3/6 per annum makes their doctors crowd these into the charities, so as to get rid of them.

It may be argued that the people who go to the Hospitals try to pay for what they receive, and that the working classes by their subscriptions to the Hospital Saturday Fund endeavour to pay their way. But the fact that a working man does not by this gift of his purchase the right to demand medical relief is well known. He does not purchase the right to go on the parish, because he has paid poor rate. And if the Saturday Fund did purchase this right for the working classes, why cannot the well-to-do givers to the Hospital Sunday Fund claim similar rewards? The fact is if our charity is genuine this *quid pro quo* would not come to the front so often as it now does. Can any one deny that it is not a common custom for the guinea or two guinea subscriber to give his "tickets" of recommendation to his servants or employees, and so save the medical fees and chemist's account? Would those who do so have the effrontery to send down to the hospital for a medical man, so that their servant might be treated free. Yet the difference would be small. It has been stated in the Annual Hospital Reports that the patients pay partly for what they receive. Well the 256,000 patients in '85 paid £6,655, or about 6d. per patient per annum, or about 1d per visit or operation, calculated at four visits to each. Considering the well-to-do classes who frequent the hospitals, these fees cannot be said to amount to much. However, it is to be remembered that the more paying patients the less chance for the genuine poor. It is really difficult to understand how good men make the "sick poor" pay over £6,000 per annum, for the charity bestowed, that is supposing it is agreed that there is "no abuse." Is the mere fact that the sum is paid, not a distinct negative to the statement made by one charity—"we treat only the 'sick poor.'"

Our eighteen medical charities in 1885, had an income of £61,482, and an expenditure of £62,812. They were in debt to about £14,451, four having a balance of £510. Their funded property amounted to £148,960; while the estimated value of their buildings were about £89,106. It is difficult to understand why they are in debt. Certainly if any other institutions were so, a close investigation would be demanded. It is well known, however, that the only healthy state for a hospital to be in is one of great debt, else how could an appeal be made to the public? This constant state of debt coupled with the fact that our hospital managers wish to increase the number of patients must suggest to the thinking public that they wish extend the parochial system, of free medical treatment and medicines to the entire community. If ten or twelve more hospitals were built, it would soon be found that there was room for a few more, and it would be shewn that people have as strong an aversion to the paying of medical bills as they have to the poor-rate, Income Tax, or school fees. Yet although there is a large machinery for working these, we are informed that there is no necessity for its application to the medical charities. The advice of a hospital committee to its medical staff is—"mind and keep up the numbers;" a falling off looks bad; in other words, thrift and provident habits are not to be encouraged. One of our local charities with a guileless simplicity, informs us that the *daily average* of patients treated is 647; this gives about seventy patients to each of their nine doctors—a truly imposing state of affairs! Yet one has a difficulty in deciding whether this statement is made so as to disgust the thinking public, or to show how worthy this particular charity is of support.

As a reason for increased support to our hospitals, it has been stated that they are required for teaching purposes. But this argument does not hold since it has been shown that the workhouse infirmaries might be utilized. Also the city fever hospitals should be used for teaching the students the different fevers. At present the law prevents the use of the workhouse hospitals for teaching purposes, but this useless prohibition could easily be removed. The fees thus acquired would tend to lessen the poor-rates.

A painful question, and one systematically ignored by hospital managers and by the clergy when preaching about our charities, that a very large number of people treated at the hospitals come there either directly or indirectly through drink and prostitution. The City Police Report of the last year states that 15,979 persons were drunk when arrested; and just as the same report states that the majority of such arrests take place on Saturday night, so the majority of casual cases crowd to the hospitals on the same day. As regards venereal diseases; the statements of the hospital reports are so drawn up as to give little useful information. But if the comparison is of any use one may state that in our Navy for 1887, and comprising a total 48,410, 7,456 men were invalided for this one disease; while in our Army,

with its 92,601, 24,731 men were on the sick list for this one disorder. If it be granted that at least fifteen others are infected by these, a glimpse will be given into this deplorably sad state, and an idea suggested of the enormous evil worked. Supposing a "storm warning" for disease were issued by our medical officer of health, would the signal not be raised on Fridays when pay day is near, and when the wage earning classes make fools of themselves by getting drunk, and when vice, immorality, and injuries follow. And if the Three Thousand could be removed off the streets, would a healthier condition of affairs not follow.

At present there is no union among our eighteen medical charities; each make and unmake their rules. Each have their annual meeting at different dates; each makes its bid for public support. One competes against the other as regards the number of patients treated. All refuse to put any restriction as to the suitability of applicants. A monopoly of the medical appointments is encouraged, thus defrauding the public of any information, which is the property of the medical profession, the subscription list has been sacrificed for the Hospital Sunday appeal; the fact is ignored that spasmodic work is bad, while organised subscribing is the best plan. People are enticed into hospitals by the "paying bed" system, and thus the deserving poor being excluded are forced into the workhouse. Entire families are lead to boast that they go the hospitals, with this effect that all efforts at thrift are swamped, and the working man is induced to yield to the influences of the medical charities or workhouse Infirmary.

Hoping that the present happy-go-lucky methods may give way to a better organisation and combination of our charities.—I am, yours,

Liverpool. ROBERT RENTOUL.

THE PROGRESS OF A YOUNG PRACTITIONER.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

THE subject about which I am to write a few words, though not bearing upon disease, has reference to those who treat it. I hope, therefore, it may not be excluded from your journal because it is not of strictly medical interest. In a recent issue of the *British Medical Journal*, there was a leading article on "The Waste and Supply of Medical Practitioners," which stated there were 826 members in the profession beyond what was requisite to keep pace with the population. Now that is a serious consideration for many young members like myself, who already are in practice, or about to begin. Most men have neither capital nor influence, and must set up wherever they think the prospects are best, and be content to labour and to wait. There are others, more favoured, who have means and buy practices. With the favoured kind I have nothing to do. What I want to know from old and experienced practitioners who have had to plod their way from the bottom of the ladder upwards, is, in what time would they reasonably expect an average man, beginning practice under similar circumstances, to make a fair competence, of say, £300 per annum? I know no definite answer can be given; it all depends upon the man and his chances. But surely there is an average degree of success which might be stated in figures at which a man of ordinary intelligence and perseverance may hope to attain. It is stated in the article already alluded to, that only 50 per cent. of the men who get qualified in a certain London school, achieved fair success in fifteen years. We are left in doubt as to what fair success is. It seems very slow work to be fifteen years making a practice worth £300 a year, if even that can be called a fair practice. In building a practice, all depends upon the man, and not his attainments. I suppose there is an average degree of success, though for obvious reasons it is difficult to get the results of each one's work. At this time it is a more difficult work to make a practice amongst a community, than it was some years ago, because, now-a-days, it is a question of who will serve the community best and at the cheapest rate, as they have a large enough supply to pick from.—I am, yours truly,

JUNIOR.

UNQUALIFIED ASSISTANTS.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

DEAR SIR,—Your leader in the last number of the PROVINCIAL MEDICAL JOURNAL entitles you to the thanks of unqualified assistants, and I think it may come under the notice of some of our representatives on the Medical Council. The scheme is simple, and if properly worked out will put an end to a very vexed question. It is quite true, as you say, that it would be an injustice to turn us out on the world without a means of livelihood. Many of us are assistants through no fault of our own, and I venture to think we are useful in our proper sphere.—I am, yours truly, AN ASSISTANT.

Manchester, January 15th, 1889.

Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VIII.] MARCH 1, 1889. [No. 87.

Our Portrait Gallery.

ROBERT BARNES, M.D., ETC.

ROBERT BARNES, M.D. Lond., F.R.C.P., F.R.C.S., Hon. Fellow King's and Queen's College of Physicians in Ireland, was born in Norwich. His father, Philip Barnes, F.L.S., was the founder of the Royal Botanic Society. His early education was conducted in Bruges, Belgium, where he laid the foundation of his skill in languages. His medical education began in his native town, where he passed a short apprenticeship under Richard Griffin, well known for his zeal in the cause of the Poor-law medical officers. He entered at University College, and then at the private school in Little Windmill-street, under Gregory Smith. To this he was led by being appointed House-Surgeon to the Queen Adelaide Lying-in Hospital in the immediate vicinity. In this hospital he began his work in Obstetrics. Resident pupils came from all the hospital schools, and Barnes assisted in their clinical instruction, attending all the difficult cases in and out of the hospital for more than a year. Gregory Smith's school being closed, Barnes was tranferred to Samuel Lane's and St. George's Hospital. Under Mr. Lane he acted as Demonstrator of Anatomy. Having passed as M.R.C.S., he went to Paris, where he studied Medicine, Operative Surgery, and Obstetrics, not neglecting general science and literature at the Collège de France and the Sorbonne, for nearly two years. He edited in the *Lancet* the lectures on "Insanity" of Baillarger, under whom he had worked at the Salpétrière. He was appointed Lecturer on Forensic Medicine at Dermott's School in Bloomsbury Square; and the better to qualify himself to teach he studied Practical Chemistry under Prof. Hoffman at the College of Chemistry.

Intimate and constant as was his devotion to obstetrics, it was not exclusive. Early in life he spent a year at sea. For fifteen years he was Physician to the Seamen's Hospital, Dreadnought. One result of the knowledge thus acquired was his Report on Scurvy in the Merchant Service to the Privy Council, made at the request of Sir John Simon, and his evidence on the same subject before a Royal Commission. His principal scientific writings are: "On Fatty Degeneration of the Placenta," *Med. Chir. Trans.*, 1851-3; "Lectures on Puerperal Fever," *Lancet*, 1865-6; "The Lettsomian Lectures on Placenta Prævia," 1867; "On the Convulsive Diseases of Women," the Lumleian Lectures at the Royal College of Physicians, 1873; "Obstetric Medicine and Surgery," in conjunction with Fancourt Barnes; "The Medical and Surgical Diseases of Women;" "Lectures on Obstetric Operations," which have gone through several editions at home and abroad, and which have probably more largely than any other work influenced modern obstetric practice. It attracted attention by the originality of the author's illustrations. He worked on the editorial staff of the *Lancet*.

Dr. Barnes presided over the Obstetric Section of the International Congress at Philadelphia in 1877. He assisted Tyler Smith in the foundation of the Obstetrical Society, and was President in 1865-6. He has been President of the Hunterian Society, and is Honorary President of the British Gynæcological Society. He has served as Censor and Examiner of the Royal College of Physicians; Examiner of the University of London, and of the College of Surgeons. The last appointment he resigned under circumstances especially honourable to himself. The Council of the College, without consulting the Fellows and Members, had obtained a Charter empowering them to grant special licences in Midwifery apart from Medicine and Surgery. The examiners, Drs. Farre, Barnes, and Priestley, were invited to examine "persons" for this licence. Dr. Barnes at once refused. This refusal entailed the resignation of his colleagues, and so the Charter became a dead letter. He has been successively Obstetric Physician to the London, St. Thomas', and St. George's Hospitals. He has also been Physician to the Royal Maternity Charity. He initiated the organisation of the Graduates of the London University, which led to their incorporation in Convocation, and representation in Parliament. Our portrait is from a photograph by the well-known artist, Horsburgh, of Edinburgh.

SUGGESTIONS FOR THE MORE RATIONAL THERAPEUTICAL TREATMENT OF RESPIRATORY AFFECTIONS.[1]

By C. CLARK BURMAN, L.R.C.P., L.R.C.S. Edin.,
BELFORD, NORTHUMBERLAND.

(*Continued from page* 73.)

BEFORE entering upon the consideration of the treatment of acute bronchitis, chronic bronchitis, with its complications, emphysema, cardiac affection, etc., and the various symptomatic disorders depending upon one or other form of respiratory embarrassment previously mentioned, it will be instructive to look at the physiological action of those drugs, and classes of drugs, which are chiefly used. I have assumed all along that belladonna and nux vomica possess characteristic properties dependent on their action upon the respiratory centre. I have deprecated the use of sedatives, and especially of opium, in the treatment of acute diseases, of the parenchyma at least, of the respiratory organs, and particularly of chronic affections when distinct structural changes, more or less permanent, exist; and in other diseases which tend to produce embarrassment of the respiratory act; so that I am obliged to point out upon what grounds I base my objections to sedatives, and those upon which I advocate the use of respiratory stimulants.

Expectorants are remedies possessed of the power of modifying the secretions, and thereby influencing the inflammatory conditions of the respiratory mucous membrane, and which facilitate in various ways the expulsion of the secretions. This latter definition is necessary in order that we may include certain drugs which owe their "expectorant" properties to their purely mechanical effect, as is well seen in the action of an emetic, say, of sulphate of zinc, or even mustard and water, in some forms of suffocative catarrh. Expectorants are usually divided into the well-known classes of depressant and stimulant. I would sub-divide the latter class into, (1) those whose action is more or less general, and (2) those whose influence is directly due to their action upon the respiratory centre.

The drugs belonging to Class I. include ipecac., antimony, aconite, calabar bean, iodide of potassium, chloral hydrate, chlorides of soda, potassium and ammonium, acetate and citrate of ammonia, steam, etc., etc. In Class II. we have squill, senega, carbonate of ammonia, the various balsams and gum-resins, etc., forming the primary division, and belladonna, nux vomica, etc., constituting a secondary division. The mode of action of the drugs belonging to Class I., and the first division of Class II., is so well understood that little need be said about it. "But it is not a matter of indifference which one of the agents known as expectorants be resorted to. In the first stages of the case the bronchial mucous membrane is swollen, congested, turgid and dry; it is hyperæmic, but secretion is arrested, and the mucus is scanty and tenacious, and got up only with the greatest difficulty. It is obvious that here one part of the treatment must be to relieve the vascular system, to reduce the turgescence, without which free secretion cannot be attained. To give ammonia and senega would not achieve the desired end. The agent to be used must be one which will affect the circulation; which will relax the cutaneous vessels and depress the circulation. Such an agent we find in tartar emetic, in iodide of potassium, or ipecacuanha. The administration of these agents is the line to be pursued until turgescence passes into free bronchial secretion, and a moist condition of the skin is secured; then, and then only, are the stimulating expectorants to be resorted to." This quotation, from Dr. Milner Fothergill's "Handbook of Treatment," gives us a rational as well as a physiological plan of procedure, and comprises the whole truth regarding the use of expectorants if we wish for success to follow their administration. It is universal in its application, and is a sure guide. When secretion is free, then squill, senega, and ammonia, etc., may be given with advantage. The indications for treatment now are to sustain the system during the exhaustive process of breathing through the obstructed air-tubes, and expelling the phlegm.

We see, then, that many of the expectorant remedies act not only upon the bronchial mucous membrane, but have a decided influence upon the system at large. Ipecacuan, has, no doubt, its specific action; but in addition, it has powerful diaphoretic and other properties which aid this action Iodide of potassium acts principally through the absorbents and depresses the circulation. The acetate and citrate of ammonia produce their good effects by dilating the cutaneous capillaries, and consequently a free action of the sudiparous glands; thus drawing blood into this area and reducing the quantity in the pulmonary tissue; but other drugs which I shall mention particularly, have a direct influence upon the rhythmically discharging centres of respiration, combined in some cases with a similar action upon the circulatory centres. To these I intend to direct attention, since to them we owe much of the good in cases beyond the power of the so-called expectorants; and from them, when used without careful consideration, we unfortunately meet with the most serious consequences.

Among the most active of respiratory depressants—that is to say, upon the respiratory centre directly—we must consider.

1. *Calabar Bean.*—This drug was proved by Professor Frazer to have a profound effect upon this centre. "After a small lethal dose of the poison, the fatal result is always due to failure of the respiration; and if the body be at once opened the heart is found still beating; indeed, it has been seen to continue to do so for one hour and a half after death" (Frazer). "The symptoms induced by the drug in man are completely parallel with those that occur in the lower animals" (H. C. Wood). Although both the respiratory and circulatory centres are influenced, the chief action is upon the former; for Professor Frazer found its effects were distinctly counteracted by atropia, which is *par excellence* a respiratory stimulant.

2. *Aconite* acts very decidedly upon this centre; and its effect is not produced by any stimulation of the inhibitory nerves of the vagus and so arresting the action of the discharging centre, but by the effects upon the centre itself;

[1] [To the writings of the late Dr. Milner Fothergill, whose recent decease the profession still mourns, I must express my great indebtedness, not only for suggesting the line of thought I have endeavoured to follow in this paper; but also, as the readers of his works will observe, by the numerous quotations, for the actual words in which to express my meaning. I take the opportunity, therefore, at this stage to fully acknowledge this assistance in a general way, and thus avoid a repetition of references. For further information I would suggest a careful perusal of the following works of Dr. Milner Fothergill: "The Antagonism of Therapeutic Agents," "Chronic Bronchitis," "Handbook of Treatment," "The Physiological Factor in Diagnosis," and "Gout in its Protean Aspects."]

because previous section of the vagi did not influence the action of aconite upon the respiration (Fothergill). "Aconite is a direct depressant and paralysant of the respiratory centres" (H. C. Wood).

This property of aconite is not, I think, so well recognized as its depression of the circulatory centres, and owing to its frequent administration in inflammatory respiratory affections, when the vascular tension is high, we should be careful to remember and look for its manifestation in case respiratory embarrassment comes on, for fear of increasing, instead of reducing it. We have the means of preventing the respiratory depression by the counteracting influence of atropia, and thus may get the effect upon the vascular, without injuring the respiratory system.

3. *Chloral* depresses all nervous action, and its influence on respiration and circulation does not differ from its action upon the nervous system, unless it be in degree. "It kills by paralyzing the centres of circulation and respiration, especially the latter" (H. C. Wood).

4. *Opium and its Derivative—Morphia* act upon all nerve centres, but especially on those of respiration. This influence is perhaps most vividly seen in cases of opium poisoning, where we do not judge of the danger by the unconsciousness, but by the state of the respiration, and all our efforts are directed to keep up the latter by artificial means so long as the heart continues to beat, which is, fortunately, the last to succumb. That this action is upon the centre itself is proved by its effects continuing after section of the vagi.

These are the principal direct respiratory depressants. As we have found that some of the depressants have their action partly upon both centres, and others only upon one, so among the stimulants we find the same.

1. *Strychnia* has a decided influence upon the nervous system as a whole; still it has been found by Rokitanski, Mayer, etc., to possess a marked stimulating effect upon the centres for circulation, and from observation of its antagonism to certain well-known respiratory depressants, chloral and aconite, we draw a favourable conclusion of its utility in diseases in which the respiratory act is imperfectly performed. Liebreich and Bennett found it exercised an influence over chloral in toxic doses, and Bennett found chloral even more potent in strychnia poisoning, for strychnia produced expiratory spasm. Leube and Rosenthal found that artificial respiration prolongs and even saves life, according to the amount of strychnia injected. "Strychnia excites or stimulates the respiratory centre, but in *lethal* doses it acts most pronouncedly upon the expiratory portion of the respiratory act" ("Antagonism of Therapeutic Agents"). This subject needs further investigation by experimentation, but clinical observation warrants the theory of stimulation of the respiratory centre, and in the treatment of chronic bronchitis with emphysema it is very useful, and gives much better results than carbonate of ammonia alone. Dr. Thorowgood strongly recommends it in cases of paralytic and emphysematous asthma.

2. *Atropia* acts upon both centres, but its influence is by far the most marked upon that of respiration, and no better proof of this is to be found than in its wonderful power of antagonising the poison of opium and aconite, in which the respiratory depression is so well marked. Professor Frazer found it to at once restore the failing respiration and circulation in Calabar Bean poisoning; the acceleration of the rhythm of each under its influence being very marked. There are numerous instances on record of the great and almost immediate effects of the hypodermic injection of atropia in cases of opium poisoning, and it is, certainly, the best treatment to adopt so soon as the stomach has been emptied. If necessary, artificial respiration must be carried on.

3. *Ammonia*—The stimulating properties of the carbonate of ammonia are so thoroughly well recognized that mention of them is scarcely needed. No doubt it is a temporary but a potent stimulant, and useful when we wish to aid quickly the embarrassed respiration. "Ammonia is an intense direct stimulant to the respiratory centres in the medulla oblongata" (H. C. Wood). For more detailed information respecting the physiological action of these drugs, as demonstrated by experiment, I must refer my readers to chap. II. of Dr. Milner Fothergill's essay on "The Antagonism of Therapeutic Agents; and what it teaches." This consideration of the physiological action of certain drugs, as retarding or accelerating the nervous discharges of the respiratory and circulatory centres, will open the way to the treatment of bronchitis.

Acute bronchitis becomes more dangerous the nearer we approach the two extremes of life; and here it is that the well regulated use of belladonna is found to be of the greatest service. That children stand belladonna exceedingly well, and require a larger dose in proportion than of most other drugs, is well known. With reference to the aged, when the low vitality calls for nervine tonics, we must remember that the vesical irritability usually met with at this time of life, is aggravated by the exhibition of one of our best known nerve tonics—strychnia—and the administration of belladonna as a substitute for the respiratory affection is strongly recommended. Again, in convalescence from an acute attack of bronchitis, when we are anxious to assist in improving the vascular condition, iron, except in its mildest forms, is objectionable for the same reason.

In the treatment of acute bronchitis of the sthenic variety, our chief indications for treatment will be regulated by the condition of the vascular tension, and, according to it, we endeavour to relieve by depressants in the first stage, so as to reduce the turgescence of the bronchial mucous membrane and permit free secretion. In adults, when conditions are favourable, I do not object to the prescription of Dovers' powder (the ipecac. counteracting the opium) and antimony, but after the skin has acted freely, and secretion has become established, I would omit the opium, and trust to one of the many expectorant remedies of Class II. I fancy that in jaborandi, or its alkaloid pilocarpin, we have a means of avoiding opium, even in the dry stage, and look for good results to follow its more extended use. But I wish to leave the conduct of treatment to ordinary principles and to turn attention to those cases which go beyond the limit of safety and give us so much anxiety; especially capillary bronchitis, broncho-pneumonia, and acute exacerbations in the course of old standing chronic bronchitis.

Much has been said about the vitality of young children, but I think my readers will agree with me that even in the strongest child the appearance of capillary bronchitis, either as a primary disease, or secondary to some other affection, as measles, whooping-cough, is a circumstance, none of us can contemplate without the gloomiest forebodings.

Dr. Ellis in his "Diseases of Children" says: "The symptoms become extremely urgent, the breathing is oppressed almost to suffocation, there is ceaseless jactitation, well-nigh uncountable pulse, a bluish cast over the features,

beads of cold sweat on the forehead. The cough is smothered and less frequent, the child dreads to speak, both because of the dyspnœa and also from the fear of exciting a coughing paroxysm. Such a condition it is scarcely necessary to say is fraught with extreme peril, and the end may rapidly come, either by coma or convulsions."—P. 295, 4th edition.

This characteristic and truthful description points to the use of remedies which will restore power to a centre well-nigh exhausted. This exhaustion is seen in the diminished frequency of the cough, and in the oppressed breathing. The child frequently is unable to lie down, but sits up looking piteously around for assistance. Here we have the quickly acting carbonate of ammonia, given in doses regulated so as to avoid vomiting (unless the evidence of accumulated secretion points to the use of an emetic, when, by increasing the dose we secure its emetic action without the depression so frequently found after other drugs, even ipecacuanha wine), and with the ammonia, tincture of belladonna and nux vomica, given freely, watching the result, and reducing the dose when the respirations become stronger and deeper, at the same time counteracting the failing energy by the exhibition of stimulants and good nutritious food. By increasing the power of the failing centre we give strength to both inspiration and expiration, points to be remembered when emphysema is present, not an unfrequent accompaniment of this disease. This, with the constant application of poultices, and a room heated to 65° and kept moist by the vapour from a bronchitis kettle, will meet every indication.

Broncho-pneumonia, or catarrhal pneumonia as it is now generally called, differs from capillary bronchitis in that it is almost always secondary to some other disease, such as measles, whooping cough, etc.; consequently we are met with urgent symptoms, intensified by the co-existing weakness resulting from the primary disorder, and rapid development of cerebral symptoms is marked, together with a much higher temperature curve than in capillary bronchitis. Though the latter is much more rapid in its course, it tends rather to a fatal issue unless speedily combated, while the former, fortunately, more frequently ends in recovery if the co-existing debility is not extreme. Here the treatment is essentially the same as for capillary bronchitis, and according to Dr. Stierlin, of Schaffhausen, who gives from five to twenty grains of carbonate of ammonia, he lost only seven out of 150 cases; but most writers recommend quinine as the best remedy for reducing the temperature without producing depression. Dr. Leonard Weber, of New York, advocates strongly the mustard bath, made by diffusing one pound of mustard in a small bath of water at 105°, keeping the child in ten minutes, making thorough friction all over the surface until the skin becomes pinkish, after which the patient is put into a warm bed. The bath relieves the congested lungs and overburdened heart by increasing the amount of blood in the peripheral circulation, also by stimulating reflexly the vaso-motor centres. In those cases where the debility contra-indicates this proceeding, and where the constant changing of poultices for the same reason is decided against, the moist girdle as directed by Vogel is very useful. A piece of flannel, two yards long and wide enough to reach from the armpits to the hips, is wrung out of hot water so that it will not drip, and wrapped round the body closely, but not so as to interfere with the respiratory movements, and the ends secured by means of pins. This moist wrapper is covered by a dry warm one, which must be changed as often as it gets wet. The inner wrapper should not be removed for several days, but be kept moist by applying as often as is necessary warm water with a sponge. A sufficiently large piece of spongio-piline would answer the same purpose; and, if counter-irritation were deemed necessary, turpentine might be sprinkled over it after being wrung out of the hot water. The administration of belladonna and nux vomica, I think, is indicated when the respirations mount up in frequency and are shallow, and should be freely pushed if any lividity of the lips shows itself; while digitalis is not unfrequently needed when the heart manifests signs of weakness.

The treatment of acute inflammatory diseases of children by repeated small doses of aconite and green hellebore, as advanced by Dr. Lewis Smith, of New York, cannot in my opinion be of great service in the diseases just considered; since, as secondary affections, they are unsuitable for the administration of such potent depressants, and quinine is probably more useful. As primary diseases, they might be met with these drugs, but their dangers are almost equal to their benefits; still, Dr. Ellis in his work speaks highly of this plan. I have myself no experience of it whatever.

Acute Exacerbations during Chronic Bronchitis.—I take this part of the subject here, though it would perhaps more appropriately fall under chronic bronchitis; but I intend my remarks upon chronic bronchitis to be more general than particular, especially as it would be impossible to enter upon the consideration of the treatment of the different forms of the disease, as well as the manifold complications and accompaniments, in a paper of this description. I wish to point out, not so much the plan of treatment to be carried out, but rather to suggest additions, in the form of drugs which we have found to possess so marked an influence upon the respiratory centre, and also to emphasise the dangers of other drugs whose action is decidedly unfavourable, and to urge their discontinuance. The objection urged by the advocates of such drugs, that the conditions at times become so marked as to render their use imperative, may be readily met by showing that the fault lies in allowing these conditions to become so imperative, as also showing how, if already existing, they may be subdued without resort to sedatives, and if sedatives are absolutely indicated, then the method of guarding them, so that their good effects are allowed to take place without permitting their almost greater dangers to become apparent. "As no acute catarrh is so liable to frequent relapses, and exhibits such a tendency to become habitual, as that affecting the air passages, so also the chronic form is especially liable either to relapse into acute inflammation with augmentation of intensity, or, on the other hand, to degenerate into blennorrhœa."—(Rokitanski.)

The importance of these acute exacerbations lies in the same fact as we found in broncho-pneumonia, that the patient is already debilitated by his previous illness, and not in a position to stand the action of potent depressant remedies. Hence our line is decidedly that of stimulation, not so much general as special. While it may be necessary to administer alcoholic beverages, we attack the already weakened respiratory centre by means of carbonate of ammonia, belladonna, or nux vomica as the case may be, though it may perhaps be judicious in the first place to reduce the turgescence of the already chronically thickened bronchial mucous membrane by means of iodide of potassium, with acetate of ammonia if the pulse be good, or ipecacuanha wine in the place of the iodide if the pulse be

feeble. In these cases we can resort to the stimulating expectorants at an earlier stage than in ordinary acute attacks. There is one thing of importance in connection with the administration of purgatives to chronic bronchitic patients with acute exacerbation. No doubt purgation may be very useful as a derivative, but the consequent exposure and liability to fresh cold must not be overlooked. Having overcome the comparatively short first stage in these cases, we have now to consider the indications for assisting the weakened respiratory act, so that the additional secretion shall be effectually dislodged and removed. For this purpose the drugs already named will have to be relied upon. The greater the amount of secretion we can remove, the better for our patient, since there is to be considered the long-standing bronchial thickening, which of itself is interfering with admission of air. When the secretion is excessive, and accumulates faster than the act of coughing suffices for its removal, emetics are to be given; but the state of the heart is not to be forgotten, and an emetic which acts speedily, leaving little depression, must be used; probably sulphate of zinc is the best. This may be followed up by a mixture such as—

℞ Liq. Atropia Sulphat., ♏i.-ii.
Liq. Ammon. Anisat. (P. Pruss.), ♏xv.-xx.
Aquam. ad ℥i. ter in die.

Or, if no vesical irritability exist, a combination of—

℞ Ammon Carb., gr. v.
Tinct. Nux vom., ♏x.
Tinct. Scillæ, ♏xx.
Infus. Serpentariæ ad. ℥i. ter in die.

"Senega is not to be used while any acute manifestations are in existence. It is one of the most stimulant substances of its class. Serpentaria is much preferable, and is decidedly superior in the matter of taste."—(Fothergill.)

Where we find the respirations mounting in frequency, with increasing cyanosis, especially if the case is one with cardiac complications, we must push strychnia and digitalis with alcoholic stimulants; and our guide must be the state of the respiration. As its rate comes nearer to normal, so we reduce our dose, or give it less frequently; and we must remember that "strychnia slows the respiration" as "digitalis slows the circulation," the slowing is a *part of the improvement*—the improvement does not rest on the slowing.

Before leaving this subject I must again allude to acute bronchitic attacks occurring in gouty subjects. Here, while we treat the bronchitis, the causal relationship of the gouty diathesis is to be attacked in addition; and alkalies must be freely administered, not only with our "*first stage*" remedies, but later on also; and it may be remembered I remarked that, perhaps, this action of the bronchial mucous membrane might partake of a vicarious nature. We may assist this effort of nature by remedies which will make the respiratory act more effectual, but our chief hopes lie in relieving the toxic condition of the blood by reducing the nitrogenous ingesta, and by bringing skin and bowels to the aid of the functionally imperfect kidneys. While on this subject I am reminded of the dangers of giving opium in acute attacks of gout, when pain is so marked a symptom. The powerful restrictive action, so to speak, of opium upon the functional activity of the liver and kidneys makes it a dangerous drug to use, and this danger is intensified if we have any respiratory disorder co-existing. Chloral, from its depressing action on the vascular system, would, upon theoretical grounds, be safer, and probably, if no respiratory embarrassment accompanied the attack, would be admissible; but my experience is strongly in favour of the hypodermic injection of morphia combined with atropia. When speaking of asthma, I quoted the experience of Dr. Oliver, as recorded by him in the *Practitioner* for January, 1876. No doubt the atropia is indicated, since we wish to increase the inspiratory power which is struggling to get the mastery of the bronchial spasm. The tendency of morphia is decidedly favourable to the reduction of the nervous energy causing the spasm, but its action upon the respiratory centre is that of a depressant, and at such a time depression is far from desirable. What the atropia does is to allow the morphia to have full scope in so far as the spasm is concerned; while its depressant tendencies are thoroughly counteracted by the atropia. In fact, some authorities recommend the hypodermic injection of atropia alone, whereby the respiratory act is so strengthened as to become the victor over the spasm; but in my opinion, the combination of the two drugs is better, since a smaller dose of each is required. I have for several years given up using a solution of morphia alone for all hypodermic purposes; and my experience is that I rarely now find a patient suffer from vomiting or headache, which so frequently occurred when I used morphia alone; and since it is much more convenient to have one solution for *all* cases, I think its advantages are still further increased. The solution I use contains $\frac{1}{5}$ gr. of acetate of morphia, and $\frac{1}{120}$ gr. of atropia in five minims; and this quantity in most cases proves effectual. In a case of acute gout affecting the right knee joint, I used to administer one and sometimes two injections *per diem* for some time, and upon no occasion did any unpleasant symptom follow its use. I should have hesitated to have given an equivalent amount of opium by the mouth. The combination materially adds to its usefulness, and is quite applicable in any case in which morphia in this manner seems to be indicated. I know that since I have used this combination, the occasions upon which my "needle" has been called into requisition have been much more numerous than before, because the after-effects are almost unnoticeable.

Acute Bronchitis.—As I have already said, I need not go over the treatment in detail of an affection, the indications for which, in ordinary cases, are so plain. I wish, particularly, to direct attention to the treatment of cases, where, from the intensity of the respiratory embarrassment, a fatal issue is speedily anticipated. Here we must push strychnia. When the patient is sinking, when death is impending from exhaustion of the respiratory centres, worn out with the sustained efforts which alone can maintain life, heroic measures are not only justifiable, but are actually called for, and strychnia must be given more freely, and in larger doses than usual. Dr. Fothergill says he would not hesitate, in a very grave case, to push strychnia till the limbs twitched, beginning with $\frac{1}{10}$ grain every six or four hours, and increasing the dose if necessary.

In acute bronchitis occurring in elderly people, the impaired vitality offers but a feeble resistance, and adynamic symptoms are apt to supervene early. Alcohol and ammonia are to be given freely, and if strychnia excite the activity of the bladder centres, increasing any vesical irritability, the substitution of belladonna will be more likely to produce good results, since its soothing effects upon these centres will relieve the patient from the annoyance and fatigue connected with the frequent desire to micturate.

The application of poultices is a matter of such great importance, taking the place, as they do, of bleeding, in a

certain manner, by dilating the cutaneous capillaries, and keeping the blood there—thus bleeding the patient into his own blood vessels—and is one which we, as medical men, cannot overlook. In all acute cases poultices should embrace the whole chest, as in the jacket form, as they can be applied and changed with the minimum amount of movement on the part of the patient, and without much exposure; two very essential conditions. As Dr. Lauder Brunton has pointed out, poultices, to be effectual, must be applied hot; but owing to the pain produced, we not unfrequently see them kept until cooled down sufficiently to the feeling of the patient. The consequences are obvious—a very short time elapses before the poultice is so cool as to become useless—an unnecessary number is applied to overcome this, with the result of fatigue and exposure on the part of the patient, which we wish to avoid. This may be obviated by placing a fold of flannel over the patient's chest, and applying the poultice upon it so soon as made. In this way the maximum of benefit is secured with the minimum of fatigue and exposure. The bad conducting property of the flannel allows the heat to pass very gradually to the skin. As the moisture of the poultice soaks through, it becomes a better conductor, and the heat passes more quickly; but the increase is so gradual as not to cause any painful sensation whatever, but only one of soothing and comfort. The poultice also naturally keeps much longer hot, and the necessity for changing it arises much less frequently. If counter-irritation is desired, the plan need not be altered, only modified by wringing the flannel out of hot water in which a certain quantity of mustard has been diffused. This is placed on the chest, and the hot poultice above, and the whole covered over with a sheet of cotton wool or waterproof sheeting. Turpentine may be substituted for the mustard. In one case of pneumonia, at which I met an old practitioner in consultation, owing to the patient's intense disgust at the odour of linseed meal, he recommended a large fold of lint, sufficient to envelop the chest, to be saturated with camphorated oil, and applied; over this, oiled silk, closely fastened by means of a few stitches to the lint below. This made an excellent substitute for the poultice, and did not interfere with the treatment of a large blister, which was subsequently applied.

Inhalations.—The value of the inhalation of steam as a means of reducing the dry and turgid condition of the bronchial mucous membrane is well recognised; but the profession is not so unaminous upon the subject of medicated inhalations, or the use of oral and oro-nasal respirators, whereby the air drawn into the chest passes through a layer of cotton wool or other material upon which certain volatile substances, such as carbolic acid, creasote, terebene, iodine, eucalyptol, etc., have been placed. Drs. Burney Yeo and Sinclair Coghill are strong advocates of the latter plan in cases of phthisis; but Dr. A. Hill Hassal asserts that so minute a quantity reaches the lungs that they are practically useless. The paper of the latter gentleman in the *Lancet* for May 5th, 1883, and again in *British Medical Journal* for November 3rd, 1883, founded upon carefully conducted experiments with (1) oro-nasal respirators, (2) vapour of hot water, (3) steam spray inhalation, (4) air spray, seem to point to the conclusion that each and all of them are possessed of little power for good. Dr. Burney Yeo, in a communication to the *British Medical Journal*, May 19th, 1884, contradicts the results of Dr. A. Hill Hassal, and maintains that, when carbolic acid is mixed with twice its weight of sp. chlorof. and used with the inhalation respirator as recommended by him, 2.5 grains of carbolic acid can be vaporised in one hour, so that, if worn twelve hours out of the twenty-four, thirty grains of the acid will be diffused into the air respired. Dr. A. Hill Hassal, in the *British Medical Journal* for January 12th, 1884, suggests a system of inhalation in properly constructed chambers, the air of which is permeated with certain drugs by means of evaporation over hot water spread over a comparatively large surface. In this way substances, possessing a low degree of volatility at ordinary temperatures, may be diffused throughout the atmosphere of a chamber with great facility.

This controversy chiefly affects the treatment of phthisis; but the application of precisely the same principles in the treatment of bronchitis, especially chronic forms of the disease, is now so largely practised, and since it promises to be so successful (at least, the clinical evidence brought forward in its favour is very great), it is to be hoped no means will be spared to make its application as perfect as possible; so that, either by means of inhalation from properly constructed respirators, or similar instruments, or in specially designed chambers, the substance employed may reach the smaller bronchi and air vessels, and bring about those desired changes in the character of the secretion which we recognise as the result of an improved condition of the surface from which it is poured out.

For the purpose of treating bronchitis, the inhalations we employ are either relaxant, detergent, or sedative. In chronic bronchitis and bronchiectasis, where the quantity of secretion is unusually great and often offensive, inhalation of carbolic acid is decidedly useful. In acute bronchitis, when the patient is cyanosed and suffering, turpentine gives excellent results, either from an inhaler, or by using a large sponge or piece of flannel wrung out of hot water and sprinkled freely with turpentine, and then inhaling the steam arising from it.

Dr. Orlebar, of the Victoria Park Hospital, says, "Tincture of benzoin in inhalation in the proportion of one drachm to the pint of water alleviates the cough, and is not without its good effects on the physical signs." "Carbolic acid, ten grains to the pint of water; excellent, having used it in every form of bronchitis, and with invariably good results." There are many other substances we may employ in this manner, suitable to varying conditions of the mucous membrane of the air passages; but in the early stages, plain steam is most grateful to the patient, and renders the viscid, scanty secretion of mucus more plentiful and easy to remove.

I have repeatedly mentioned the dangers of sedatives in cases of respiratory embarrassment from any cause whatever, but in chronic bronchitis, perhaps, more than in any other disease, is their use contra-indicated, or only admissible upon certain conditions—that they are combined with some other drug which shall counteract their respiratory depressant properties.

Let us take opium first. I have, in an earlier part of this paper, mentioned its physiological action upon the centres of respiration; I wish now to consider its effects upon other parts of the economy. Opium interferes with tissue change. Opium restricts, nay, almost entirely stops that function of the liver connected with the metamorphosis of the peptones brought direct to it through the portal circulation. As peptones they would fail to build up the tissues. They must be rendered insoluble by the liver, and elaborated into the albumin of the liquor sanguinis, or passed into bile acids

or urine solids. Albuminuria is not unfrequently due to the passage of peptones unchanged into the circulation, and is free from the dangers which we attribute to the presence of this substance in the urine. In a mild form it is often found after a hearty meal, when the excess of peptones is passed out of the body without undergoing further elaboration. If this essential element in tissue regeneration is absent, or present in unduly small proportions, the inevitable consequence is, that in time the system wastes, but in chronic bronchitis the muscular part of the body to which we are most indebted for the maintenance of life is comprised in the muscles of respiration, ordinary and extraordinary, and the cardiac muscle. Should any of these fail for want of nourishment the effects are soon noticeable; and most of all are we interested in the diaphragm and heart. In this then lies an additional danger in the use, especially the continued use of opium, a danger increasing ten-fold when any gouty condition co-exists with the bronchitis. We must never forget the elaborating function of the liver and the eliminating function of the kidneys, both of which are most seriously interfered with by opium. Bromide of potassium is also contra-indicated on account of the potash being a muscle poison, depressing the heart and diaphragm too much. If the indication for a sedative be marked, bromide of ammonium must be employed. Choral hydrate is perhaps the most dangerous, its depression affects respiration and circulation. There is one important point to remember about this drug, although without doubt it is the most useful hypnotic we possess when vascular tension is high and pain is great (I refer now to its ordinary use)—viz., the warning of Sir Crichton Browne, who says: "The energy of the action of chloral, as measured by its minimum fatal dose, is in proportion to the development of the cerebral hemispheres. In micro-cephalic idiots again, I have noticed that a proportionately larger dose of chloral is requisite to induce its physiological effects than in persons with fully developed brains." This must be borne in mind when prescribing the drug, and our knowledge of its danger in highly intellectual patients will guide us as to the dose to be employed. It further throws a light upon some cases of fatal poisoning with comparatively small doses of chloral.

Another property of chloral is its power of reducing the temperature of the body. This is due to the dilatation of the cutaneous capillaries—the heat losing area. This effect, together with the reduced activity of the circulation, and consequent impaired chemical interchanges, makes it a most dangerous drug to use in chronic bronchitis, when, owing to the slow oxidising processes, the body temperature tends to fall. The amount of oxygen in the blood of such patients is not sufficiently large to admit of those rapid and incessant chemical changes on which the body temperature is almost entirely dependent. In one case of poisoning by chloral recorded by Dr. Levinstein, six drachms having been taken, the temperature fell to 92°. Belladonna on the other hand raises the body temperature, and its administration in cases of alcoholic, opium, chloral, and aconite poisoning, in which we meet with extremely low temperatures, and in the collapse of burns, is strongly advocated; for by it we excite the acts of circulation and respiration which are so greatly depressed.

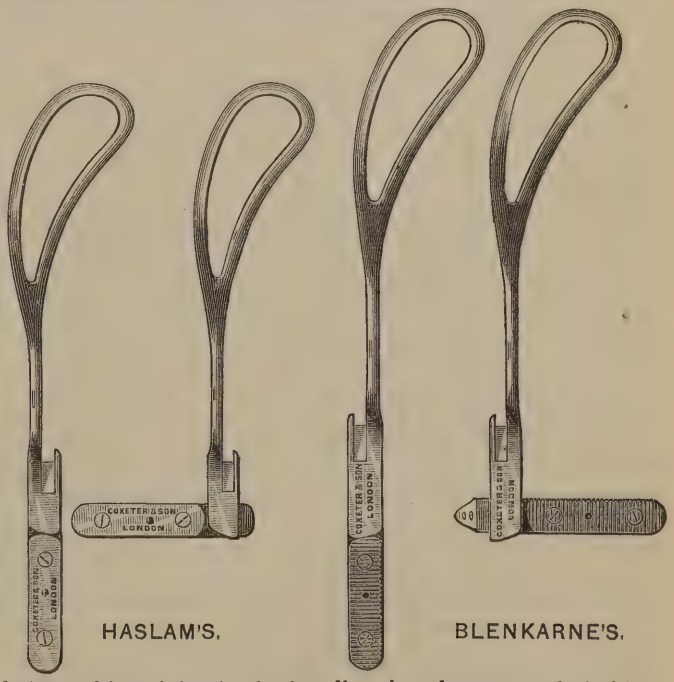
This short review of the additional properties of some of the respiratory depressants will not fail, I trust, to emphasise the grave responsibility attached to their administration in severe respiratory embarrassment. When the blood is charged with excess of carbonic acid, or is deficient in oxygen, the excitability of the discharging centres of respiration is aroused, and it is upon the response of the auxiliary respiratory muscles thus called into action that the danger is overcome, and the blood sufficiently aërated to be consistent with life. Now, in chronic bronchitic patients, this condition of the blood is more or less persistent; but the centre accommodates itself to the changed order of things, and the body generally shows evident signs of the change in venous engorgement, which is marked in the cerebral vessels, and results in the impairment of the mental processes, which become slow or defective, the mind is clouded yet irritable, indications pointing to an ill-nourished brain from the impure state of the blood. This is the condition best suited for the dangerous effects of sedatives to show themselves in their most aggravated forms, or for small doses to produce results attained only by much larger doses, under different circumstances.

(*To be continued.*)

AN IMPROVED MIDWIFERY FORCEPS.

By W. L'Heureux Blenkarne, L.S.A., M.R.C.S.

Although of the various shapes and sizes of midwifery forceps it may be said that their "name is legion," very little, if anything, has been done to make the long forceps a less cumbrous and unwieldy instrument, especially as regards the adjustment of its upper (or anterior) blade. There are, indeed, Dr. Haslam's forceps (*vide* illustration), in which the upper blade can be shortened during adaptation by there



being a hinge-joint in the handle; but, however admirable the general construction of these forceps may be, they are absolutely useless to those practitioners who (like myself) "put on" the lower blade first, as the "lock" of the lower blade is posterior—*i.e.*, the lower blade itself is anterior, thus making it utterly impossible to adjust the upper blade secondarily (at any rate without a great risk of damaging the rectum). Then again, the handle of Dr. Haslam's forceps

is made to bend backwards towards the perinæum, where it is in the way.

Now in the forceps which I have invented (*vide* illustration, which represents the upper blade of each of the said forceps) the handle is arranged to bend forwards towards the pubis, where it is not only not in the way, but, on the contrary, when bent, it forms a good "grasp" for the hand when adjusting it on the fœtal head. With these forceps, although they are slightly longer than "Simpson's long" (Dr. Haslam's being about an inch and a quarter shorter than Simpson's), the adjustment of the upper blade is not only simplified as regards the obstetrician, but (and this is a most important gain) *all necessity for moving the patient to the edge of the bed is avoided*, there being no handle to get in the way of the mattress; *in fact, it is as easy to put on these forceps as it is an ordinary pair of short forceps.*

The beautifully clear and exact engraving which accompanies this article is taken from a photograph, the scale being three inches to the foot. The general design of the forceps may be described as Barnes' forceps with Simpson's handles, the steel surface of the handle of the upper blade being slightly corrugated. My design and instructions have been most painstakingly carried out by Messrs. Coxeter and Son, from whom the forceps may be obtained, and I feel sure that any practitioner who invests in a pair will not be disappointed in the simplification I have hereby effected in thus doing away with that "bugbear" of many obstetricians—"putting on the upper blade."

SOME PRACTICAL POINTS REGARDING THE USE AND APPLICATION OF ORTHOPÆDIC INSTRUMENTS.

By NOBLE SMITH,
SURGEON TO ALL SAINTS' CHILDREN'S HOSPITAL, LONDON.

EVERY surgeon who deals with orthopædic cases certainly should master the mechanical details of construction of the apparatus which he intends to use, if he wishes to command success. I never send a patient to the instrument maker, but as a rule take the measurements myself and give my directions as to carrying out the apparatus personally. This plan saves the patient an immense deal of trouble and expense, and moreover is, I believe, the only way in which orthopædic surgery can be practised satisfactorily. Then as regards "fitting on" and alterations. It should be a rule of practice that an instrument is never to be considered as an apparatus which is to act by itself. It is a *means of treatment* by which the surgeon, as in the case of using splints for a fractured leg, can treat his patient. With this view the steel, or whatever metal is used, should be alterable to the fullest extent by the surgeon himself. Steel is the lightest material which in the majority of cases we can use consistently with strength and elasticity, and this metal can now be tempered so accurately, that while it does not bend by fair usage by the patient, yet it can be altered in shape by the surgeon by means of wrenches. In some cases aluminium can be used, but for the necessary stability it has to be made so thick that very little economy of weight is effected, and the bulk is objectionable. Aluminium can always be bent to a certain extent by the surgeon, but it will not bear the amount of alteration which can be effected with well tempered steel. If instruments are made upon this principle they can as a rule be finished off at first ready for the surgeon to apply, because the fitting can be done by him with the wrenches before referred to. This fitting and the subsequent alterations are essentially matters for the surgeon to attend to. The requirements of the case are before him, his knowledge of the objects to be attained, the manner in which they can be attained, the anatomical difficulties to be encountered, and the degree to which the parts will bear coercion, are purely surgical matters, and can only be acquired imperfectly by a pure mechanician.

By practising in this manner hardly a day passes but we may be able to simplify an apparatus or add to its efficiency. I will now proceed to describe an instance for the application of these principles. Let us take a case of talipes equinus, in which the muscles of the tendo Achillis are permanently contracted but otherwise healthy, and the anterior muscles of the leg paralysed, as in the case of which Fig. 1 is a drawing. Here division of the tendo Achillis is demanded, and whether we reduce the deformity at once, or in two or three efforts, or more slowly as some surgeons advocate, in any case the necessary temporary support of the part can be effected by means of a simple padded iron splint, which can be bent by the surgeon to the required angle. Fig. 2 represents the same foot as in Fig. 1 after division of the tendo Achillis, and with the iron splint applied. The bandage is displaced from the centre of the foot to show the splint and padding. The splint is usually covered with linen or other material. When the union of the tendon is sufficiently firm for the patient to begin to walk again, a less simple apparatus is required, and for this purpose, it is necessary to have a steel support attached to the boot upon the side to which there is any disposition for the foot to turn, and a T strap upon the opposite side. Thus, if there should be a disposition to varus the steel is placed at the inner side, and if the inclination is to a valgus position the steel should be upon the outer side, the T strap checking the inclination. It has been considered necessary to have a rack-joint to the steel support opposite the ankle, which can be gradually moved by a key and the foot improved in position. A rack-joint is an expensive one; moreover, when the patient has walked about for a time and requires more freedom of movement in the ankle, a new instrument has to be made with a limited movement to the joint, and with a back-stop to prevent the foot from dropping into

Fig 1

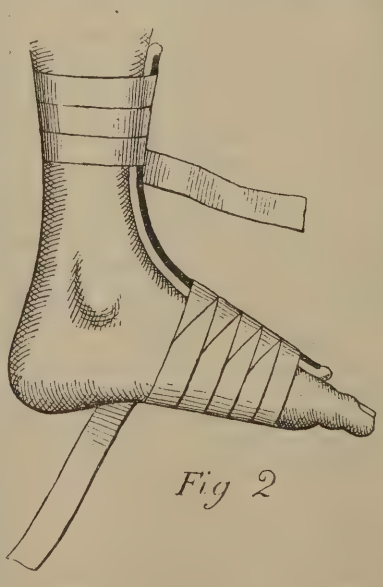


Fig 2

its former position, for it must be remembered that the anterior muscles are paralysed, and that artificial means are necessary to keep the foot at a right angle. Much expense is thus incurred, and some degree of trouble to the patient, from the several alterations. To simplify these proceedings I have devised the following plan.

Fig 3.

Fig. 4.

The ankle joint of the instrument is made as it will be required when the patient can walk with some freedom of movement, that is, with a back stop joint (this he will always require so long as the anterior muscles are paralysed), and with a limited degree of forward movement. The joint is then fixed by means of a steel peg piercing the two pieces of metal, A in Fig. 4. The dotted lines show the outline of the lower part of the instrument which fits into the upper part. The first cost of the instrument is less than one with a rack joint. The peg projects and can be easily removed with pincers when the time arrives for so doing. The instrument is thus altered in construction at once when necessary, at no extra expense, one instrument taking the place of two. When the patient has so far recovered strength in the tendo Achillis that free flexion of the foot may be safely allowed, the front partial limit of movement can be filed down in a few minutes, and therefore the apparatus need not be kept inconveniently long by the maker for this alteration. The dotted lines in Fig. 4 also show the application to this instrument of the plan by which the upper part can be separated from the lower, by simply bending the instrument until the two parts are at a right angle to one another, a position which cannot occur when the apparatus is in use. The chief object of applying this kind of joint (which is not new) to this instrument is again one of economy and convenience.

When a joint is a permanent one—*i.e.*, not detachable—one of two plans must be followed for fixation to the sole of the boot. Either that must be a fixture, or there must be a box socket in the boot for the instrument to go in and out of. In the latter case the parts soon wear into a loose condition, while when the instrument is permanently fixed into the boot, it can only be worn with one pair of boots, and one set must be made for each pair of boots in use by the patient. By having the detachable joint as shown in Fig. 4, each pair of boots which the patient is required to wear has only to have the lower part attached, and the upper portion will do for every occasion. This may seem a small matter, but the absolutely necessary expense and trouble of these cases are so great, that whenever we can save the patient unnecessary cost, I think it is our duty to do so.

In conclusion of this paper, which is intended to be *suggestive* of the *principles* which I think should guide the orthopædic surgeon, I would add that a paper upon the rules which I suggest should guide orthopædic surgeons in their practice, was contributed by me to the last International Medical Congress, held at Washington, and is published in the *Transactions* of that Congress.

ON SOME OF THE MORE COMMON DISEASES OF THE BREAST, WITH THEIR DIAGNOSIS AND TREATMENT.[1]

By Edward Bellamy, F.R.C.S.,
surgeon to charing-cross hospital.

I have taken the liberty of slightly altering the subject as announced in our syllabus, inasmuch as "Diseases of the Breast" might well occupy us for some indefinite period. I therefore take this afternoon such cases as most frequently are under the notice of the general practitioners, and should time permit, go a little further. Too little is made of small ailments, in surgery as well as in medicine. Let me first take the cases most likely to be met with, I would say, in anatomical sequence, and possibly outside the hospital clinique—at least, such cases as would be admitted.

Neuralgia of the Breast, or *Mastodynia*.—This is a condition, I think, not made enough of in the ordinary text-books; it is a serious one, and often gives rise to most anomalous symptoms, which may be very masked. Little is known of its pathology. Functional activity of the sexual organs seems to be its chief cause; also hysteria, uterine trouble, anæmia, or habitual constipation; locally, possibly injury, or wearing tight corsets. It is not always that we can detect any structural change in the breast or its surroundings by palpation (Sir A. Cooper's "Irritable Tumour of Breast"), and in the event of our being able to do so, the symptoms are much the same, as before stated. On touching or handling the region, the pain is severe, not confined to the breast, but radiating over the shoulder, down the arm, back, and loins, possibly. A consideration of the connection of the nerves supplying the breast and the plexuses will readily account for this. Patients suffering acutely will shrink away instinctively on the approach of the surgeon's hand, much in the same way as a patient with rectal fissure instinctively dreads examination. The patient cannot lie on the affected side; the weight of the gland seems intolerable; stays and bedclothes may be unable to be borne; nausea is frequent or persistent; the symptoms are always aggravated before or during the catamenia. If we can *feel* anything on breast palpation, it is generally in the form of some small, movable, sensitive nodules, which cause great alarm to the patient or doctor, may be, from the idea that she has a cancer—a common conclusion in every female mind if anything is wrong with the breast. I need hardly say that in such a case there is no enlargement of the axillary glands—an important point in diagnosis. I have never met with these symptoms *before* actual puberty, though perhaps on its immediate verge, *i.e.*, when the gland is *becoming* active.

Treatment.—A nodule, if detected and persistently painful, had better be removed, but there may remain pain

[1] Abstract of Post-Graduate Lecture at Charing-Cross Hospital, January 25th, 1889.

in the cicatrix, accounted for by neuritis. Cases purely hysterical require, of course, moral and mental treatment. Attention must be given to any uterine displacement, which should be reduced, and the condition of the rectum carefully attended to, *e.g.*, piles, scyballa, fistula, fissure. Locally, I have found the glyceride of belladonna, or the emp. belladonna, of great use, at the same time giving full doses of quinine and bromide internally. Change of air and scene, in single women with certain tendencies; marriage, if possible, and moral restraint.

Diseases of the Nipple and Areola.—True eczema is by far the most common. It is similar to eczema in any other part of the body, most frequent during suckling, sometimes associated with scabies, and most obstinate. Any possible source of irritation must be investigated, and the urine examined on the suspicion of gout—gouty eczema, in fact.

Our Treatment is local and constitutional. I have found belladonna and lanolin, or glycerine, very useful; also lotions of nitrate of silver or lead, or dusting subnitrate of bismuth over the part, or boracic acid, and the *primæ viæ* attention to diet, and, if gouty, appropriate remedies.

Paget's Disease of the Nipple.—I mention this here as it is generally called an "eczema." At all events it most closely resembles it in appearance, but is a precursor of cancer. According to Paget the cancer (carcinoma) is developed in the gland from one to three years after its appearance. We must be most careful in our attempts at the true diagnosis. The areola is "like the surface in a very acute eczema." When ulceration takes place it ends in destruction of the nipple. The ulcer is indurated at its base. No treatment is of any use. Paget suggests that "it is advisable to anticipate the development of cancer by removal of the gland when it is met with in women about the age when cancer is likely to develop, and especially where there is strong hereditary tendency" (Beck).

Cracked Nipples.—There is no doubt the subject of cracked nipples and threatening inflammation of the mamma is a great deal overlooked. The troublesome cracks generally appear in women who, after each time of suckling, expose the breast, or fail to cleanse it of the irritating saliva of the infant or the putrifying milk. In young women with a first suckling there is generally a great intumescence of the nipple; it is hyperinjected and florid; in shape it often seems to spread out, mushroom-like, and is very tense. In women who have borne children and suckled them the nipple is more usually conical, but still prone to cracks, or ulcers; the cracks, after all, are merely confined or constricted ulcers, very much of the same condition as met with in the rectum. They may be traumatic—*i.e.*, caused by friction or over-sucking—or it may be the result of the fatigue caused by suckling, rendering it necessary to discontinue it. This condition of things not unfrequently leads to abscess, which is generally quite local and confined to the areola, but it may pass on to mammary abscess.

Treatment.—Utter cleanliness is clearly the first thing. The application of a concentrated solution of boracic acid is of great value. An india-rubber nipple-shield should be used. I have found the best application, by far, in glyceride of tannin—this should be applied immediately *after* suckling, and then the parts protected till the next occasion by a Wansborough's leaden nipple-shield. Mind to have several in use, and to thoroughly purify them by keeping them immersed in some antiseptic solution. A good suggestion is to strap the threatening gland *firmly* on the second day after confinement, and in a few days to remove it, and use an inunction of ext. of belladonna and iodide of potash, giving iodide at the same time internally.

New growths in the nipple and areola are very rare. Epithelioma has been met with, and cases of atheroma in the areola have been recorded clearly developed in its glands.

Wounds.—I need hardly detain you with wounds. Of course they must be treated as wounds in every other part of the body. We must carefully bear in mind the undoubted fact that breast injuries, however apparently insignificant, "light up" malignancy, and we must be ever on the look out for this contingency. I speak more particularly of blows. Cuts or stabs must be treated on ordinary principles, but here again they may be factors in more serious after-conditions, as every hospital surgeon can call to mind and prove.

Acute Engorgement of Mamma.—I cannot say I have ever seen these cases, at any rate with any certainty in diagnosis. We must be on our guard should such cases come before us, and be prepared to differentiate them from others more common—*e.g.*, hypertrophy. As described by Ledentu and Verneuil,[1] it would appear to be a rapid swelling of the breast, with induration, occurring in oldish women, and recurring after some weeks or months, possibly associated with arthritis (gouty).

Erysipelas calls for but few remarks. Its diagnosis is well nigh obvious, and it must be treated on general principles. As a primary affection it is rare, and its streptococcus propagates by preference along the lymphatics; but in the advanced condition it permeates the finest interspaces, giving rise to superficial or deep lymphangitis, which is slight or severe. In the event of action going on, suppuration is imminent, and poulticing and antiseptics necessary. When abscess has formed it must be treated according to proper principles, but we must bear in mind the specific nature of the pus and *débris*. According to Dr. Park, a good local application is made of a combination of naphthalin, ichthyol, and lanolin, or possibly ordinary white paint, with iron internally. This naturally leads me on to the consideration of

Acute Inflammatory Affections (acute mastitis, mammary abscess, milk abscess).—This condition is sometimes met with in young adolescents of both sexes, but naturally more common in the female. The diagnosis is easy, and it may be said to be *the* characteristic breast disease of the unimpregnated female, or, may be, delicate and anæmic male, between sixteen and twenty. The mammæ often give trouble at puberty. Suppuration often occurs.

By far the most common acute inflammation is that associated with lactation and pregnancy, and most frequently occurs in those who nurse their own children or in primaparæ, generally about the first month, and in anæmic patients, poorly nourished, and with prolonged suckling. Of course any confinement is a predisposition. It is said to be more common on the left than the right, and is generally retro-mammary.

Causes of Lacteal Engorgement.—Eczema may be a cause, but the abscess due to it is invariably subcutaneous, and we must remember that scabies is not an uncommon cause, the breast being a seat of predilection. Cracked nipples are often a cause, the inflammatory products being transmitted by the operation of the lymphatics. I may

[1] Quoted by Park, in "American System of Gynæcology and Obstetrics," 1888.

mention that traumatic abscess is invariably situated in the bulk of the gland.

Chief Symptoms of a Typical Case.—"There is 'stiffness' and soreness in the lower region of the mamma, usually about three weeks after confinement, rigor, generally fever-high temperature, hot skin, quick pulse, loaded tongue, whilst thirst and headache are often present. The inflamed lobules become hard and knotty, while the breast throbs and feels as if ponderously heavy. The affected lobules soon run together into one hard swelling, over which the skin becomes tense and somewhat livid. If suppuration occurs there is often another rigor, with perspiration, while the skin over the mamma becomes œdematous and splits on pressure" (Banks).

Treatment.—Physiological rest. The child should not be allowed to suck, and this applies to both mammæ. The milk should be drawn off with the breast pump. In robust women, depletion, etc.; tonics in the anæmic, etc. Locally: slinging, fomentations, belladonna, and glycerine. Abscess impending, poultices. Chronic indurations may remain, and it is very important that all remains of inflammation be removed, as is well known carcinoma is not an infrequent result of mastitis, leaving some indurated lobes or lobules. I have on several occasions removed the entire gland, or what remained of it, when riddled with old sinuses, on this principle. I have seen several cases where neglect has clearly set up malignancy.

Chronic Lobular Inflammation.—This is certainly a condition which may give rise to the greatest difficulty in diagnosis, from the fact of its being so often mistaken for malignancy: I allude to the condition of hardened, detached lobules in the breast, generally of slow progress, not always attended with pain actually, but always with uneasiness, and giving rise to great anxiety. We may find, possibly, a simple nodule greatly indurated, and even to the most skilful hand, closely simulates carcinoma. However, the integument is *non*-adherent, and does not, when "pinched up," to use the felicitous expression of Banks, look like "pig skin." Again, we generally find more than one lobule involved, possibly the whole mamma greatly indurated, whilst there is no invasion of the lymphatics or glands. The catamenia seriously affect the condition—a point in diagnosis. As regards the benign tumours, I cannot think there is much to fear: our present case is retrograde (*vide infra*). This condition is often associated with neuralgia (*vide supra*); and here the pain shows itself—generally neurotic, of course, and certainly adding a great deal to our difficulties in eliminating cancer in our diagnosis. The mere handling on the part of the patient is sufficient to elaborate the symptoms to such an extent that one may be justified in puncture or incision. The result, of course, determines our action.

Treatment.—Here our treatment is a plus element in diagnosis. Tonics, etc., attention to general health, investigation of uterine troubles, local application of belladonna, will soon clear up any difficulty, and eliminate true growths from the category. [The lecturer here gave the normal anatomy of the fasciæ of the mammary region, and their influence on the definition and progress of abscess, referring his hearers to his special lectures on the matter.]

Abscess.—Its diagnosis certain, it must be opened at once—strictly antiseptically, spray used for choice, the swelling carefully washed with carbolic soap, and afterwards gently sponged with one in forty carbolic lotion. The precise spot being determined on, a long thin bistoury should be boldly pushed in, radially with the areola, and the incision so freely made as to allow of the speedy evacuation of the pus. The purified finger is next gently passed into the wound, and the entire abscess sac explored. A drainage tube must now be introduced and secured, and the usual antiseptic dressing applied. My experience is that a slip of protective to prevent "sticking," and a large pad of salicylic wool over all, is quite sufficient.

Chronic Abscess.—This has always been, and always will be, a "crux" in diagnosis at first, and may almost occupy a place by itself, as apart from acute inflammation in suppuration, being often mistaken for neoplasiæ, especially carcinoma; in fact, its history, clinically, appears to be identical—the oft-quoted "retraction" of the nipple, as pathognomonic of cancer, being almost invariably present. I well remember being present when one of the first diagnosticians of the day was deliberating as to a case which he had no doubt was cancer; and proceeding to remove the tumour, making his lower incision first and boldly into the mass, the spectators—myself among them—were speedily convinced that a hard, tense, chronic abscess had been opened. All the better for the patient! Yet, clinically, this case presented every symptom and feature of malignancy. I never saw the case after, but I have no doubt the breasts became "noduled" with sinuses (it was before antiseptics), and was ultimately excised, as a *locale* or "foyer" of cancer.

(*To be continued.*)

LARGE ABDOMINAL HERNIA, WITH ADHESION OF THE CONTENTS TO THE WALL OF THE SAC—CURED BY THE OPERATION OF INVERTING THE SAC WITHOUT OPENING IT, AND OF STITCHING THE RECTI MUSCLES ACCURATELY TOGETHER IN THE MEDIAN LINE.

Under the care of William Alexander, F.R.C.S.,

visiting surgeon to the liverpool workhouse hospital.

[Report and Sketches by A. Blackwood, M.D., Senior Resident Medical Officer.]

S. B——, æt. twenty-four years, was admitted into the hospital on June 15th, 1888. About two years previous to admission, abdominal section had been performed on this patient for double pyosalpinx. On that occasion, she made a good recovery, and was discharged from the hospital, the wound being soundly united. The patient was a stout, healthy looking young woman. She stated that her health was good, but she had come to the hospital in order to "have something done for a tumour," which, on examination, was found to be an abdominal hernia. Regarding its formation, she said, that about twelve months after the performance of the operation already referred to, she observed a "small lump" at the lower extremity of the cicatrix in the abdominal wall. It gradually increased in size, and she endeavoured to repress it by means of tight corsets, etc., but failed. Eventually, it had increased to such an extent, and caused her so much discomfort, that she determined to come to the hospital in order to obtain relief. The hernia was situated in the middle line of the abdomen, between the umbilicus and pubes. Its shape was an irregular oval, and it was slightly pendulous when the patient stood upright. At its base, on a level with the surface of

the abdominal wall, it measured seven inches in circumference, and, following its outline from above downwards, it measured twelve inches. Occupying the centre of its upper half, was a vertical cicatrix, about three and a half inches in

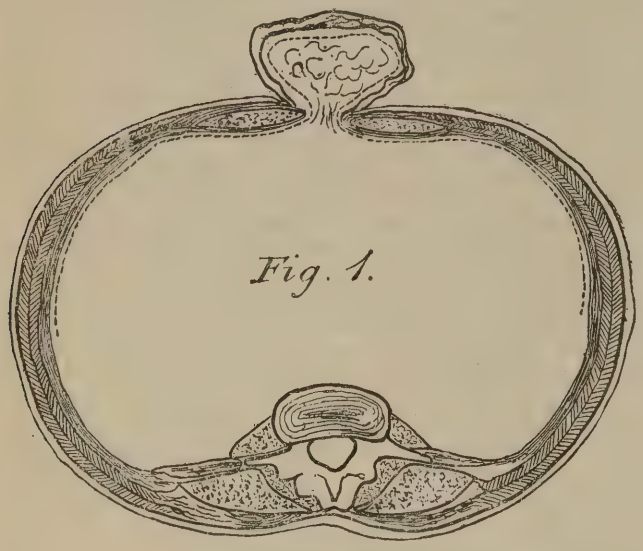

Fig. 1.—Before Operation.

Diagram showing space between the recti musles, and peritoneum and intestines protruding. The dotted line is intended to represent the peritoneum.

length, and half an inch in width. The hernia was soft and elastic, and became prominent and tense when the patient coughed. After the reduction of the hernia—which could easily be done by manipulation—the boundaries of the aperture, through which the intestines had passed, could easily be recognised by the finger.

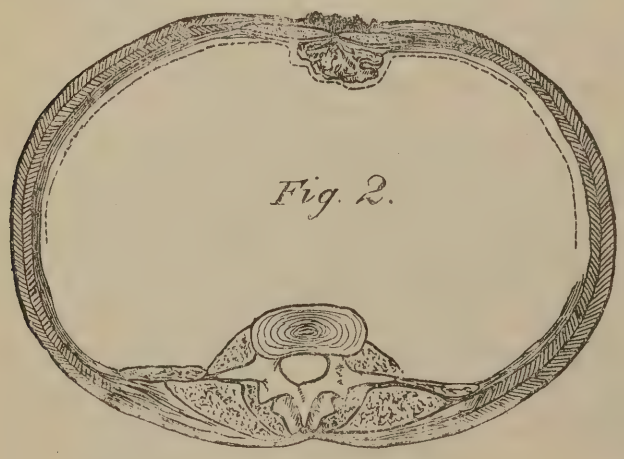

Fig. 2.—After Operation.

Showing recti muscles in close apposition; and between them and the now *inverted* peritoneum, a mass of cicatricial tissue. The dotted line is intended to represent the peritoneum.

The patient readily consented to operation, which was accordingly performed in the following manner:—She was placed under the influence of chloroform, and an incision about three inches in length was made over the sac and including part of the old cicatrix. The skin and subcutaneous tissues having been cut through, the underlying structures were successively divided on a director, until the peritoneal sac was reached. The contents and sac having been returned into the abdominal cavity, it was found that the aperture was formed by the "falling apart" of the recti muscles, their inner edges being the lateral boundaries of

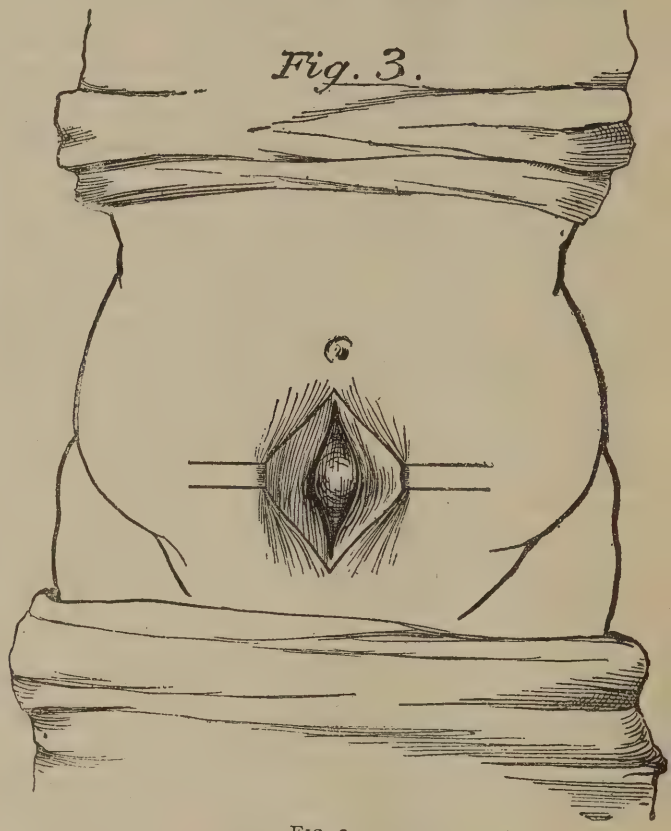

Fig. 3.

Skin and subjacent tissues held aside by retractors, showing the space between the recti muscles, with the peritoneum bulging into it. It represents the stage of the operation in which the hernia and sac have been returned into the abdominal cavity, and the recti muscles have been dissected from the neighbouring structures.

the space. The space was oval in shape, its vertical diameter being about two inches in length, and its transverse diameter about one inch. The inner edge and a portion of each muscle were then carefully freed from the neighbouring structures, and brought together, being secured in this position by sutures of silk-worm gut. Drainage of the deeper cavity—that behind the recti muscles—was provided by inserting a rubber tube between the muscles, at the lower extremity of the wound. The interior of the more superficial cavity was "dusted" with iodoform, and carefully packed with antiseptic gauze, the skin wound not being sutured. Antiseptic pads were laid on outside; these were kept in position by strapping, and the whole secured by a firmly-applied binder. During the operation, and at the subsequent dressings, antiseptic precautions were adopted.

Two days after the operation, pus began to discharge in considerable quantity from the deeper cavity. The wound was dressed daily, at first twice, so long as the discharge was profuse, but afterwards only once. On each occasion the

cavities were washed with a solution of perchloride of mercury (1-2000). The discharge, though decreasing in quantity till it ceased, continued for a considerable period; and the deeper cavity, which was at first of considerable size, gradually filled up, and finally closed. A portion of the skin sloughed, and was removed. The more superficial

Showing the edge of the recti muscles brought together and sutured. The drainage tube is inserted between the third and fourth sutures, counting downwards.

cavity gradually "filled in" from the circumference towards the centre, a very firm cicatrix being the result. An abdominal belt was ordered for the patient, and she was discharged from hospital on September 10th, the wound being firmly united, and presenting a slightly concave appearance, a marked contrast when compared with the immense mass which protruded from the abdominal wall when the patient was admitted.

Remarks.—The contents of the sac in this case were intestinal, as the distended small intestines could be readily felt under the skin. The adhesions seemed so general that none of the intestines could be pushed out of the sac into the abdomen without palpably taking a part of the wall of the sac with them. Therefore the operation of opening the sac and freeing the adhesions would have been in this case a difficult, and, in proportion to the difficulty, a dangerous operation. Although the patient, a vigorous girl, was willing to run any risk to be rid of what to her was a most distressing condition, yet, from a surgical point of view, it would have been a grave mistake to perform a major operation for what was only an incumbrance. That operations of expediency should only be undertaken when safe, is not a bad rule for surgeons to follow. The sac was easily inverted, and the fingers, pushed into the inverted sac, could easily explore all the interior of the abdomen within their reach. The operation consisted in carefully dissecting the skin from the sac, and inverting with the fingers the denuded sac, in the same way that had often been done before the denudation was carried out. The recti muscles were then brought together in the middle line, and stitched together over the inverted sac. A drainage-tube was passed between the recti at one point to drain the sac, and then the skin was brought into position.

The operation answered all the expectations that were formed of its safety, ease of performance, and utility, and can be recommended as suitable for all similar cases. There are cases of hernia where the sac and its contents are capable of inversion, where adhesions are extensive, and their removal consequently difficult and dangerous, and where the aperture is such that it can be closed by the approximation of muscular tissues. Ventral herniæ occurring after operations will most frequently fulfil all the indications. In reducible hernia of this class, it is a question whether the inversion of the sac would not be preferable to the ligature of the neck of the sac, or to the cutting off of the sac and re-stitching of the margins of the opening.

AN ENQUIRY INTO THE CURRENT THEORIES OF THE CAUSES AND NATURE OF ACUTE RHEUMATISM, AND THE TREATMENT GENERALLY ADOPTED FOR ITS CURE.

By Alexander Harkin, M.D., F.R.C.S.,

consulting physician, mater infirmorum hospital, belfast.

(*Continued from page* 82.)

That in any discussion on a controversial subject, such as the salicyl treatment of acute rheumatism, an appeal would be made to the numerical method, "which but to guess a 'Louis' made immortal," was a very natural conclusion, and that hospital statistics, as superior in the matter of numbers, careful tabulation, and uniformity of treatment to private returns, should be utilised for the purpose was as correctly assumed; and hence we have had presented to us, chiefly in the columns of the *Lancet*, at various times, most valuable contributions from eminent London hospital physicians. But, important as are the numerical method and the law of averages, in their application to clinical medicine, we cannot regard their teaching as the expression of pathological laws, being themselves subject to perpetual exceptions, and, as a learned writer already referred to says, "They are at best but generalised expressions of degrees of frequency."[1] Dr. Sibson, formerly of St. Mary's Hospital, London, in his address in medicine at the Newcastle-on-Tyne meeting of the British Medical Association, when referring to his treatment of a number of rheumatic and gouty patients, emphasises this weak point in the numerical method thus: "In the examination of those cases, I shall avoid all comparison of them with the group of cases of these diseases observed by other physicians, and those previously treated by myself in the wards of the hospital. How can

[1] Dr. Walsh's address in medicine.

you compare one set of cases with another? Each patient has his own character, and his disease presents its own peculiar feature; cases unduly severe or unwontedly mild are apt to come in groups extending over a long period, and the strict comparison of one series of cases with another becomes therefore impossible.[1]" But it was perfectly legitimate to accumulate a mass of facts gathered by independent observers, and arising under similar conditions, such as was presented to the Clinical Society of London by the late Dr. Headlam Greenhow, and the leading hospital physicians, at the discussion in the Royal Medical Society, and for others to entertain the conviction that if ever hospital statistics could settle the question then presented for debate, the occasion and the men were there to accomplish it. That these elaborate returns, supplemented by the comments and conclusions of their compilers have succeeded to any apparent extent in so doing is however too much to admit.

The essayists as a whole, excluding the president of the Clinical Society, although in their formal conclusion at the end of their communications they maintained the powerlessness for good of the salicyl compounds in the prevention or the relief of the most lethal symptoms, yet expressed their approval of its use, their firm conviction of the curative agency of the drug. This inconsistent proceeding appears to an outside observer, in the quietude of his study, as a remarkable characteristic of the whole discussion in the Royal Medical Society, for, while nowhere perhaps could there be found men more free from conscious prejudice or bias, there was in the statement of almost every speaker evidence of a tendency to protect the character of the drug, as a mother would defend her offspring, however ungainly, or, as if actuated by the spirit of the well-known districh—

> Be, to its fault, a little blind!
> Be, to its virtues, very kind!

This delicate handling of the subject was plainly manifested in the attempt to explain away the frequent recurrence of relapses, so characteristic of the salicyl treatment of acute rheumatism, and the preference of ideas to facts when the latter told against some of the assumed gifts or properties of the fashionable remedy. Thus while Dr. Sidney Coupland did not question the truth of the fact that relapses are vastly increased under this treatment, he advanced the specious explanation that they may be promoted by a too early transition from a milk to a solid dietary, or by a too early getting out of bed, by change of air, or abeyance of rest, even when using the salicylates, etc.; while in the same debate the latter, in trying to account for the protracted recovery and feeble condition of the convalescents, complains that the salicylate patients are now kept far longer than formerly on low diet, and confined to bed after the subsidence of the disease *for fear of relapses!* If Dr. Fagge's complaint be well founded, what becomes of Dr. Sidney Coupland's excuse; surely if low diet and rest in bed are practiced unduly, with the expressed object of preventing relapses, how can the neglect of these precautions be fairly charged with their production; and surely these provocatives of relapse under the salicyl treatment are just as operative under every other plan, even under the nihilistic treatment. But the discussion at the Royal Medical Society is full of such contradictions.

Again, the reluctance to accept hard facts when opposed to preconceived ideas is well exemplified in the observations of the president himself, at the winding up of the debate. On that occasion he is reported to have said: "Turning now to another part of the subject, I myself do not—in spite of those most interesting, and of course accurate, tables which have been brought before us by Dr. Gilbart Smith—believe that the salicylates increase the frequency of heart disease. On the contrary, I quite coincide with the hope and and anticipation expressed by Dr. Fagge in the early part of the discussion, that when salicylates are brought to bear upon the fever in the first days of its existence, we shall see a notable diminution in the heart disease, for in my own experience it has been exceedingly rare to see heart disease springing up."[1] Here we have proof of reluctance to accept facts, when opposed to ideas, hopes, and anticipations, although the president's matured experience on a more recent occasion found vent in very impressive, cautionary terms, warning his hearers of the danger he had witnessed from the perfunctory administration of the antipyretic drug.

But the unwillingness to subordinate our convictions to the hard logic of facts was not confined to the members of the Royal Medical Society in conclave, as we find the editor of the *Lancet* testifying that, "in spite of the unfavourable conclusions which Dr. Headlam Greenhow felt compelled to draw from his elaborate and critical analysis of his series of cases, communicated to the Clinical Society, there is certainly no evidence that these remedies are losing ground in public favour, as they are being employed more than ever!"[2]

In spite! is the favourite expression of proofs adduced by most competent observers, credulity and practice go hand in hand, uninfluenced by such vulgar considerations as bare facts. Dr. Fagge himself confessed "that before he made these investigations—of which the results were before them—he was strongly biassed in favour of the medicine, but that the opinion was forced on him by his clinical experience, and that if his figures had even suggested a doubt on the mind, he would have candidly admitted it." Unconsciously to himself, however, the spirit of the "decided advocate" dominated his paper, and the skill of the pleader was well exhibited when treating of the incidence of cardiac affections and the influence of the drug; for he says, "although in 69 of 355 cases, auscultation revealed some change in the character of the heart sounds while the patient was in hospital, he could hardly find one in which there was reason to believe that *pericarditis* set in at a time when the action of the remedy was fully established. Almost all of them were cases in which at one period or another a systolic murmur was detected, and he believed that considerable doubt often hangs over the interpretation of such sounds." Now the incidence of pericarditis, which was paraded by Dr. Fagge, is comparatively of rare occurrence under ordinary treatment, even under that limited to rest in bed and blankets. For instance, Dr. Sibson, the advocate of this passive treatment of rheumarthritis, states that out of seventy-four patients treated in St. Mary's Hospital, only six suffered from pericarditis; while of the seventy-four, only one-fifth escaped from endocardiac inflammation. Then as to the interpretation of the cardiac sounds,

[1] *Medical Times and Gazette*, Aug. 13th, 1870, paper 187.

[1] It is notable that Dr. Gilbart Smith's field of observation comprised 1748, and the president's 90 altogether.

[2] *Lancet*, July 4th, 1882, p. 190.

and the doubt cast by Dr. Fagge on their importance, he is most fitly answered by Dr. Sidney Coupland, in his analysis of his eighty-four cases: he states that these bruits were present in a remarkably large number of cases, only twenty out of the whole in which they were not detected. I am not prepared to say that all of the apex murmurs were due to endocarditis, but I cannot differentiate them; and if in those cases where the murmur faded, and excluded from the category of organic change, there still remains a number largely in excess of the proportion usually noticed. Dr. Hilton Fagge's manner of dealing with the cardiac troubles of acute rheumatism reminds one of Boyle's remark: "These dialectic subtleties that the school men employ about physiological mysteries more declare the wit of him who uses them than increases the knowledge of sober lovers of truth."

It is much to be regretted that this important enquiry had not been conducted on a uniform basis; it was perhaps impossible in the nature of things, and under the circumstances, and the different constitution and internal arrangements of the larger hospitals, and the varied aspects from which the observers regarded the mode of enquiry. How could a uniformity of result be reasonably expected when even in the primary stage of the enquiry a different starting point was adopted: thus, Dr. Headlam Greenhow laid down the rule "that no patient should be put on treatment until he had been from twenty-four to thirty-six hours in the wards, and then only when it seemed clear that his illnesss was running an acute course. He wished to exclude such cases as would, independently of any medicine, improve rapidly after admission into hospital, and become convalescent in three or four days." He had thus sixty well-developed cases on which to try the efficacy of the drug; and after closely and carefully watching its effects in every case, he gave a decidedly hostile opinion as to its suitability for the cure of acute rheumatism. Dr. Donald Hood limited his investigations to cases occurring under thirty-five years; while Dr. Sydney Coupland returns comprised patients ranging from ten up to sixty years, and treated by salicylates from the day of admission to hospital. Some of the prominent speakers in the discussion took umbrage at Dr. Headlam Greenhow, because he had not the prevision or good taste to conduct the enquiries on the plan initiated nearly two years subsequently by the first speaker, adopted by the second, and approved of by the third; apparently while they could not question the accuracy of his statistics, because his mode of examination and its results told heavily against the value of the remedy in well marked cases.

After careful perusal of the discussion, and the formulated conclusions of each speaker, one may ask what has been the practical gain to the etiology or the pathology of the disease? absolutely nothing of importance. The reader of these numerous "vertical columns" of statistics, on which the structure of salicism so much depends, remains as unenlightened as ever on the fundamental principles of causation; while the gain to the therapy of the disorder amounts to this, that those portentous piles of statistics have indisputably proved, what has always been conceded, the anodyne and cooling properties of salicine; while they have, as firmly established, its powers for evil in trebling the tendency to relapses, its total impotence in prevention or cure of pericardial or endocardial inflammation, the cardinal element in the disease, its uselessness in hyperpyrexia, its lingering recoveries and anemic convalescence, not to mention the frequent occurrence of epistaxis referred to by other authorities. An excellent opportunity was lost for settling the burning question of the relative importance of the subjective symptoms of pain and pyrexia, and those "hidden processes," always present although not always recognised, till resulting in organic valvular impairment. Can it be reasonably expected that any substantial progress will be made in the treatment of disease, where there is no agreement as to its primary, its remote or proximate causes, when those so-called complications are regarded by one class of authorities and practitioners, such as Pfeuffer and Hueter, Graves and the present writer, as the primary lesions and the joint affections, the pleuritic, pericardial, meningeal, as the natural developments of the disease; by Bristow as part and parcel of the attack, who asserts "that the heart may be regarded as one of the joints, being as liable to suffer as any of them;" or with the followers of Davies, that the disease and the virus are concentrated in and near the neighbourhood of the joints, requiring only local counter-irritation for its removal and cure. Coming to some of the statistics, let us take, for example, table III. of Dr. Hilton Fagge, in the first column of which he triumphantly proves that 50 per cent. of his hospital patients get rid of these fever and articular pains within five days after the commencement of treatment—but "Qui Bono," the relief, if their pillows were haunted by what an American writer calls "the grim spectre of relapse," and if the shadow became reality in at least 36 per cent. of those semi-convalescents—the enemy returning in these cases with redoubled violence, as if to make up for his abrupt expulsion, and in several cases, in the same individual, asserting his supremacy again and again, even to the fifth and sixth time, leaving his victim pallid and exhausted after his final departure.

Perhaps none of these returns exhibit the relapsing power of this nostrum more clearly than those presented by Dr. Donald W. C. Hood, who gives the particulars of 350 cases treated without salicylate, and with only nineteen relapses, and also of 350 other cases treated with this drug, marked by sixty-six relapses, his conclusion being that the effects of the salicylates were unstable, as relapses among patients taking these medicines were vastly increased. Among the many remarkable items in the debate, we find that after only two orations of the ten hospital physicians had been delivered, the third speaker said that he was justified, without waiting for the eight other speakers, in assuming and announcing that in connection with some other returns forwarded to himself from provincial hospitals, that the matter had been practically settled in favour of his *protége*, and declared also that the evidence of these statistics was highly favourable to the salicylic treatment, and agreed with all that has been written by observers in all parts of the world; further he intimated that in the history of practical therapeutics, there is no more remarkable circumstance than the unanimity and rapidity with which the salicylic treatment had replaced all other methods of treating acute rheumatism.

These observations, if applied simply to the diminution of pain and pyrexia, cannot reasonably be objected to, and if these two items in reality constitute the disease; and that in his calculations the less always includes the greater, his case is proved to the hilt. I am really of opinion that when Dr. Maclagan pronounced this oration, this idea was paramount in his mind, for in the same discourse he pro-

claimed the inefficacy of the salicylates in all the grave incidents of the disease, and that he had quite eliminated from his mind all consideration of cardiac disease. These are his own words: "Whether or not the salicylic treatment of acute rheumatism diminishes the frequency and danger of heart complications, is a point on which I have not time to enter, I believe that it does to some extent." This is, perhaps, the most outspoken declaration in this debate, of the insignificance attached to mere heart affections in the treatment of rheumatic fever; but Dr. Maclagan is not alone in his cavalier treatment of central diseases, as the readers of the *Lancet* can testify, as they may have seen that the Senior Physician of Charing-cross Hospital in a post graduate lecture on "Acute Rheumatism," after dilating upon the thrice-told virtues of salicylics, and declaring that no fresh light has been shed upon its pathology or treatment during the last few years, when casting a glance at the possible co-existence of cardiac symptoms, dismissed the subject in this off-hand manner: "When cardiac mischief arises in a case of acute rheumatism, it should be treated in accordance with the plan adopted in such cases, the consideration of which is outside my subject!" That subject being "acute rheumatism." I could epitomise his whole lecture in three lines; but I shall not undertake the task![1] There are many other points in Dr. Maclagan's address, as well as in the discussion, open to legitimate criticism, such as the malarial origin and influence in the disease, etc., which time does not permit me to notice, but I cannot pass over his assumption that his remedy can cure acute rheumatism, not by its antipyretic action, but by some special influence on the rheumatic process, whatever that may be, that it is, really antirheumatic and not antipyretic, and his chief argument is, "that, whereas, were the action of the drug manifested through its antipyretic properties, the fever would first be reduced, and the joint pains subsequently," he alleges, "that all observers are agreed that relief of pain and alleviation of the local symptoms of acute rheumatism precede the fall of temperature under the salicylic treatment; were the curative effect of the salicyl compounds dependent on their antipyretic action the reverse would be the case, the fever would be allayed first, and the rheumatic symptoms would decline later. The salicyl compounds put a stop to the inflammation of the fibrous textures, and all the symptoms, local and general, to which that inflammation gives rise, such an action is more fully described as antirheumatic than antipyretic, for the febrile disturbance is secondary to the local inflammation, and not the local inflammation to the febrile disturbances."

But what say the doctor's *confrères* in the discussion to this doctrine, this point so much relied on for the proof of his hypotheses? Dr. Sidney Coupland does not appear to submit to his proposition. He says, salicylate of soda is certainly antipyretic, and, to a certain degree, antirheumatic, thus giving precedence to its antipyretic properties. Again, treating of the duration of pyrexia, he says, "As there is not by any means an invariable connection between the subsidences of the pyrexia and the disappearance of joint pain, and in cases uncomplicated by pericarditis, or visceral inflammation, I have thought it well to separate these two main features of rheumatic fever in the hope that one may be able to show whether the drug has more influence over the pyrexia than over the articular inflammation, or the reverse. Speaking generally, I can quite corroborate the statement made as to the very striking amelioration produced by the drug in the severity of the joint affections; but also, as a general rule, it will, I think, be found that its influences over the pyrexia is even more striking, and that the pain in the joints persists for a shorter or longer period after the temperature has become normal." And referring to the subject of relapses, he gives statistics proving that there were frequent examples of relapse or recurrence of pyrexia in the absence of joint pain, and of relapses of joint pain without and co-existing pyrexia.

Dr. Warner's results on this point are of a negative character. He shows that the persistence of pyrexia under salicylic treatment in 190 cases averaged 5-5 days; while the duration of joint pain under similar conditions averaged 5-3 days. Dr. Warner's statements scarcely sustain the proposition advanced by Dr. Maclagan, and as judged by the evidence submitted to the Royal Medical Society, we may fairly pronounce a verdict of "not proven." One circumstance worthy of notice is, that although Dr. Maclagan had the opportunity at the close of the debate to challenge the accuracy of these hostile statements, there is no record of his having considered it necessary in the interest of his theory or the broader grounds of scientific truth. It would not be natural to suppose that these paradoxical statements would pass by unquestioned, and to the honour of the profession one voice at least made itself heard in earnest protest against the inconsequential conclusions, so unwarranted by the premises arrived at in the discussion, and Dr. Davies, a leading authority on the question much discussed, referring to the debate and the contribution of Dr. Hood writes thus: "Dr. Hood, in his able analyses of statistics of cases treated by the salicylates, deduces the important fact that of 350 cases treated by the salicylate, 241 had heart disease; and of 350 not treated by the salicylate, 247 escaped from that complication;" and he significantly adds, "What advantage there is does not appear to be on the side of the salicylate." And again, while admitting that the employment of the salicylates shortens the duration of pain, he observes from the records that relapses are vastly increased, and shows that while patients lose pain, they are left feeble and exhausted after the use of the remedy; and Sidney Coupland's conclusions are almost similar. Here, therefore, we do not obtain much encouragement for the use of the salicylates, if we consider the shielding of the heart from endo or pericarditis to be the great object of treatment. In my mind, any plan which fails in in this object is only a delusion and a snare; for while the salicylates no doubt naturally relieve the pain and fever, they leave the heart a prey to the affection, and allow it to become crippled in its action for life.[1]

But a truce to criticism. I do not cite these writers for their singularity of speech; they but represent current phases of medical opinion, often very unstable, and too much influenced by every "wind of doctrine." I only regret to know that so many have forgotten in this particular the teaching of most of the eminent pathologists of the age, forgetful of the lessons of past experiences, and of *post-mortem* appearances. While, therefore, I cannot conscientiously join in the Io Pæans offered up by the members of the Royal Medical Society and others at the shrine of the goddess Salicina, I have not the same objection to intone a canticle in her praise, composed by a countryman of

[1] *Lancet*, November, 1887, p. 951.

[1] *Lancet*, February 11th, 1882, p. 249.

mine, Samuel Lover, who with the inspiration and prevision of a true poet, apostrophised the lady some thirty years ago in a versicle, beginning:

Sally silly, silly Sally,
Sally, won't you, etc.

But, in sober earnestness, I am more solicitous of inviting the attention of your readers to the pronouncement of a sound physician living in the pre-salicylic era (1880), who, in the following weighty words viewed the convictions and opinions of his compeers—I mean Dr. Sibson, F.R.S., then Senior Physician of St. Mary's Hospital, London. Writing of rheumatism under the heading of "The Heart," he says: "It will have been seen from what I have just said that when I am looking at the inflamed joints in acute rheumatism, I am thinking of the heart. How can it be otherwise? You see the limbs powerless, every joint swollen, tender and painful, and the expression of deep suffering on the face. The first turn of the mind is to find relief for that external pain. But you know, that within a given number of days you may count them on your fingers; those limbs, now so inflamed and shapeless, will soon lose their suffering, return to the symmetry of their form, and retain their power, and with it the strong desire to escape from their enforced weariness and exercise that power. But you know that, while the outworks are thus visibly attacked, the enemy is already in the citadel; and that this disease, which in its very nature attacks the limbs, in its very nature attacks the heart also, and at the same time that it attacks the limbs—that is to say, almost or quite at the beginning of the illness. In my cases, exactly one half were afflicted with inflammation of the heart; and in nearly every one of these that inflammation pronounced itself, by the immediate language of the heart itself, by pain in its region, by the anxious expression of the face and its dusky or glazed hue, and by the disturbed breathing. All these may not be present at once, but they come in their order. And I would here say that the murmur made by the blood passing in the wrong direction through the crippled valve is by no means the first indication in point of time. In most of the cases of endocarditis contained in the paper now in your hands, the murmurs were heard from the first. But some of them presented a much more impressive and more certain chain of evidence of the inflammation going on within the heart than if you at once heard over the organ a murmur without that disturbance of the powers of life that always accompanies the disease during its acute stage.

(*To be continued.*)

CHOLERA AND DISEASE VIEWED IN RELATION TO EVOLUTION, CONTINUITY, AND MOLECULAR THEORY.

By Wm. H. Pearse, M.D. Edin.,

Senior Physician, Plymouth Public Dispensary.

The longing and striving of the mind for the perception of the order or Forms of the phenomena by which it is surrounded is part of its very nature. Indeed, if we hold the conviction of cosmic evolution, we must also hold that our desire for grasping orderly and wide general truths is as absolute an existence as are the adaptations and correlations of the sense organs and mechanisms, to physical environment. Bacon says "that Saloman . . . declareth not obscurely that God hath framed the mind of man as a mirror or glass, capable of the image of the universal world, and joyful to receive the impression thereof, as the eye joyeth to receive the light; and not only delighted in beholding the variety of things and vicissitudes of times, but raised also to find out and discern the ordinances and decrees which throughout all these changes are infallibly observed" ("Advancement of Learning," vol. iii., p. 265, Spedding's edtion). Again, Bacon says: "For certain it is that God worketh nothing in nature but by second causes; and if they would have it otherwise believed, it is mere imposture, as it were, in favour toward God, and nothing else but to offer to the Author of truth the unclean sacrifice of a lie" ("Advancement of Learning").

Herschel says: "Yet it must be remembered that as far as our experience has hitherto gone, every advance toward generality has at the same time been a step toward simplification. It is only when we are wandering and lost in the mazes of particulars, or entangled in fruitless attempts to work our way downward in the thorny paths of applications, to which our reasoning powers are incompetent, that nature appears complicated. The moment we contemplate it as it is, and attain a position from which we can take a commanding view, though but of a small part of its plan, we never fail to recognise that sublime simplicity on which the mind rests satisfied that it has attained the truth" (Preliminary Discourse, par. 393). Herschel further says (*op. cit.*, par. 10): "We must never forget that it is principles, not phenomena—laws, not insulated independent facts—which are the objects of inquiry to the natural philosopher. As truth is single and consistent with itself, a principle may be as completely and as plainly elucidated by the most familiar and simple fact, as by the most imposing and uncommon phenomena." Babbage says ("Ninth Bridgwater Treatise," p. 32, 1837): "All analogy leads us to infer, and new discoveries continually direct our expectation to the idea, that the most extensive laws to which we have hitherto attained converge to some few simple and general principles by which the whole of the material universe is sustained, and from which its infinitely varied phenomena emerge as the necessary consequences."

Following these axioms in philosophy and method, we may be justified in seeking the expression and rate of the great Form of energy or motion, whose differences make the differences of the powers of such bodies, *e.g.*, quinine, nicotine, strychnine, etc., and, indeed, of the infinite variety of organic products.

It is inevitable that the mind seek the laws or Forms of such phenomena, and that it should work by analogy and deduction, equally as it works by the enumeration of facts. It is inevitable also that the mind make numerous partial and approximate attempts to seize the full Form and generalisation. To have perceived that the chemical—in all the fulness of that word—the vegeto-biological, the animo-biological, and the diseased phenomena, are all in continuity, is in itself a grand advance in method. But not only so, for if we could interpret the law or Form of a cell, we should be able to express the whole law or Form of the organic evolution, just as the physicist extends the law of a falling body to the whole realm of celestial mechanics. Nay, further, the imagination and hopes of man, and his higher feelings, would find scope and place within the infinite and future possibilities of the yet evolving Form of life, of which his individual being is an actual, reciprocal, and even creative part. Thus the law or Form of the evolution of a cell is *the* problem of our age; its interpretation will at once place biology, both in health and disease, within the divine realm of order.

There must be a grand cosmic Form of energy and motion becoming life. All our differentiations must be partial and secondary to the pan-diffused capacity for life. Thus the eye, ear, sensation, etc., are but differentiations of the pan-diffused capacities of protoplasm: nay, further back than the protoplasm, they were latent modes of the yet earlier energy and motion. The great fundamental sexual energy, power, or motion, correlates, and is inseparable from all the senses, and from the imagination and mind. Are we not in danger of a false method, when we assume distinct structural systems of organs for reflex nerve actions? We see the sexual energy arouse in reciprocacy and continuity with all the senses and imagination, but we do not look for differentiated nerves in these processes; the energy is pan-genetic in every molecule. If these views of the pan-diffusion of our best demarked senses are just, we must apply them to our general diseases —the great fever groups, the exanthemata, the epidemics of pneumonia, pleurisy, dysentery, cynanche, cholera, etc. Nay, further, such general views, from the study of the cosmic evolution of a cell and of the organic, and from the study of the continuity of the phenomena, must be applied to the great group of nerve disorders, from the wildest insanity to epilepsy, to hysterico-epilepsy, to hysteria, and to the thousand and one neurotic forms of illness which prevail in our age. We have also been taught the continuity of growths, " . . . that every pathological structure has a physiological prototype" (Virchow: "Cellular Pathology," Lecture III.)

Thus, then, whether we view the "general" diseases, the groups of nerve diseases, or the obviously structural diseases, we see their continuity with the physiological; but we further see that great common Forms and changes must be at the base of all the species of each of the great genera. I know that yellow fever periodically is epidemic in British Guiana; also I know that cholera epidemics have happened in the same colony. We all recognise that they are very different diseases as species, but they are very near generically, for we have seen cholarine, cholera-like ague, cholera-like bronchitis, cholera-like remittent, etc. The field of mere observation does not present us with absolutely or nearly demarked different diseases, even in our seemingly best separated diseases: pathological continuity equally as physiological is everywhere apparent. What does all this mean? The greater reply is, that the protoplasm is ever dying, but that at periodic intervals the degrees of death, or devolution, or change, are in excess, and inharmonious rates follow and are established—diseases. But as we acknowledge the physiological and pathological continuity, must we not go further back and deductively assume nearly-related vito-chemical Forms and changes which are common to the varied groups? Thus we look for an approximative parallelism between disease and vito-chemical changes. We are sure, further, that the latter *must* be orderly, *must* be in continuity with the molecular chemistry of what we call the organic kingdom; and we are no less sure that, faithfully following the "historic sense," many of our diseases will be proved to be orderly, and to have great and common vito-chemical Forms and bases. A scientific and wise therapeutic practice would follow.

Life must be cosmic and eternal. The Eastern poets and philosophers saw this great idea: ". . . and in thy book all my members were written, which in continuance were fashioned, when as yet there was none of them" (*Ps.* cxxxix. 16). The Hindu idea of Brahme implies the eternal energy, continuity, and evolution. Life is the result of all preceding and existent energy and its modes; and all the past and present are in continuity.

Diseases are in orderly continuity with health; they are the expression of the contained capacity for libration which exists in the order and rates of the organic series and evolution. Disease may be viewed as orderly reversions of the previous evolution; the tendency to disease is ever absolutely present. Life and its functions, or phenomena, are neither in the blood nor nerves nor brain, mainly; life is pan-cellular, probably a pan-motion of the ultimate molecules. The pan-cellular activities are in a vastly higher state of molecular motion in some fluids, tissues, and cells, than in others—*e.g.*, the blood, with its countless living elements, its red, and its colourless Norris-discs, and its white corpuscles, is nothing less than an infinite universe of infinite activities, and of an inconceivably delicate equipoise of correlation. Its protoplasm and modes must contain the latent motions capable of the full differentiations of the future animal—eye, ear, and also the latent capacity for these yet higher differentiations by which we know and rejoice in what the senses give us, and in the yet higher *à priori* transcendental consciousness. But the infinite activities of cosmic evolution which have resulted in, and are existent—in absolute continuity—in the blood and in its protoplasm, are existent, more or less, in all the differentiations of the body. Men have died in Demerara of yellow fever from a mental shock; men have died in India of rapid cholera from mental and other shocks. Have we not all experienced the horribly fœtid, probably albuminoid putrefactive gases which evolve and escape from some women when under shock or semi-syncope? Have we not known men seized with sudden stinking diarrhœa following chill or shock? and have we not known them relieved by a full dose of cold spirit and water? In all these so-varied examples, must not our pathology embrace the conditions, motions, and disturbances of the blood and protoplasm? and must not our therapeutic "grog" also have modified, perhaps sustained or restored the normal modes and motions of, the ultimate protoplasm? When you are in Bengal or Guiana, and see the evolution of cholera and yellow fever following a very great variety of changes of environment, the mind is compelled to seek the pathology of these diseases, far more in the disturbances of the infinitely delicate equipoise and correlations of protoplasm than in any single external event.

But although we know *à priori* that all such disturbances and diseases are absolutely orderly, yet as they are disturbances of the greater Form of health, our first enquiry should be:—What is the *normal* natural Form, or law, or order, or rate of the evolution or development of a cell, and thus of the organic world?

(*a*) It must be orderly, or by what we call law, and must be cosmic in its correlations.

(*b*) It must be *part* of, or in continuity with, the Form of the evolution of the so-called elements.

(*c*) It must be in continuity with the Form of the "conservation of energy," and with the Form of the "correlation of the physical energies."

(*d*) The Form of gravitation is the same in the evolution of the spheres as in a drop of water, and it must preside over the form of a cell or a monera.[1]

[1] "All monera, when unusually disturbed, when abnormally irritated at their surface, tend to assume the globular shape," Dr. E. Montgomery

(*e*) Gravitation and chemical action are of one series.[1]

These ideas and facts, this method, must be part of the basis of the study of the Form of vital evolution, whose past, present, and future must be of one great Form of continuity. But protoplasm is not the result of one simple series of chemical rates, though its Form must be as orderly and definite as are the changes of H_2O from gases to water. Albumen is found to be "compounded of many albumens, having *very nearly* the same composition . . ." (On "Fermentation," by Schutzenberger, 4th edit., p. 255). We recognize the parallelism or continuity between what we call the organic chemical groups of bodies and living organisms—*e.g.*, we see the alcohol compound-radicals in their different modes or motions, passing through the vast series of substances of which plants and animals are composed.

In the molecular energies of C O H N, in conjunction with those of some mineral elements, and in conjunction with the cosmic modes and energies, of which the elements themselves are parts; and in conjunction with the physical energies or modes—heat, light, polarities, etc.—are the necessary and inevitable *motions* which pass into life. But these organic and inorganic elements are not final forms; they are but stages in the cosmic evolution. They are not the cause of life; they are the essential media, or modes of energy and motion passing, in absolute continuity, to the vital modes and motions. They are transitional modes of matter, energy, and motion. They could not exist without life (in one or other of its modes) any more than life—as our senses can recognise life—can exist without them. Compare a living animal in the infinite fulness of all its powers with the same just killed by a sudden blow or shock—what is the difference? We can reply but little more, than that motion has ceased in it; but motion in a living animal implies, not the circulation of the blood only, but an infinite activity of motion, reaching every ultimate molecule, every ultimate atom, and every "gemmule" of the organism, and these, in all their motions, have ever cosmic correlations. The vital phenomena are as absolutely under the law of the "conservation of energy" as are the more elementary modes of matter and motion—heat, light, magnetism, etc. The doctrine of continuity further compels us to submit our minds to the hypothesis that every molecule, every gemmule, every function of the body is a necessitous survival, of and with infinite correlations. We do not, in our present stage of method, doubt that the entire mechanical motions of the furthest heavens are in one mutual, inseparable harmony of correlation. We do not doubt the great Form or law of definite proportions in chemical actions; nor must we doubt that all the phenomena of life—of composition, structure, and function—are absolute survivals or essential correlations in and of cosmic evolution, and that they are the necessary expression and result of law and order. Viewing life thus, as the expression and result of the infinite and eternal preceding evolution, and viewing the infinite agencies whose result is life, and viewing the amazing activities ever in process in protoplasm, we shall not be surprised that the harmonies of correlation are not absolutely and identically stable. We therefore should *à priori* expect that at periodic intervals, many kinds of change of external environment would lead to a disturbance of the delicate equipoise of the molecular motions and correlations of protoplasm, and diseases thus evolve. Thus change of season, change of place, changes of wind, sudden rains, sudden heats, emotions, chill, etc., have been the occasion for the evolution of new and inharmonious motions and compounds, which in India have been followed by cholera. Very similar changes in external environment have, in other latitudes and countries, led to the evolution of yellow fever, typhoid, etc.

We are thus led to approach diseases, not viewing them as so many entities, but proceeding by the historic sense we apply the truer method of continuity, and thus we shall see affinities between so-called different diseases; whilst our therapeutics will tend to grow commensurately subtle and orderly, as is the process of the evolution of disease itself. The method of continuity further compels us to view the deviations of disease as of one order and series with the primary and fundamental evolution of protoplasm. Disease is thus, not in any case, a fixed quantity, but an orderly gradation with health—*e.g.*, no disease can be more varied than what we call cholera. The field of cholera embraces a pyrexia only, the slightest diarrhœa, the occurrence of cramps only, a remittent-fever type, with slight collapse, the slightest diarrhœa and retching, but with sudden collapse and death; the existence of a continued fever, in many, at later stages. Even bronchial attacks and other diseases will, at times, assume a choleraic aspect. Further, observation has proved the *de novo* evolution of cholera, and yet further, observation has proved that the molecular motion of the protoplasm and cells, etc., of cholera, can be taken on or absorbed, at times, by the molecular motions of other individuals. These outer aspects of the phenomena of cholera find a harmoniously parallel theory in vito-dynamic chemistry, which advances, that new motions, and for the time being, inharmonious chemical compounds arise, in true continuity, in and of the dynamic modes of protoplasm. It is obvious that out of the vastly complex, cosmically correlated and highly atomic pabulum of protoplasm, a graduated series of dynamo-molecular chemical gradation of changes must happen, which are parallel with the varied but related phenomena and symptoms of disease. This graduated series of vito-chemical change, I have illustrated by the example of the marked varieties and gradations of cholera, typhoid, and the febro-inflammatory groups—cynanche, pneumonia, herpes, etc.

Some general propositions have to be kept in mind:—(*a*) That the laws of the primitive protoplasm, prevail throughout

(St. Thomas's Hospital Reports, ix., p. 76). The forms of shells can be exquisitely drawn by an arm attached to a vibrating pendulum. The exquisite and infinitely varied figures thus produced demonstrate the great place of gravitation in the production of animal forms.

[1] "They (the oxygen atoms) are urged towards it (a red-hot diamond suspended in a vessel of O) by what is called chemical affinity; but this force made clear, presents itself to the mind as pure attraction of the same mechanical quality, if I may use the term, as gravity" ("Heat as a Mode of Motion."—Tyndall. 3rd edit., 1868, p. 46). "The magnitude of the forces engaged in this atomic motion and interior work . . . . is enormous." "The force of gravity almost vanishes in comparison with these molecular forces" (*op. cit.*, p. 139).

"Like the molecules, the erections of man present every gradation of stability, from that of the pyramids to that of the lofty, wide-spreading gothic arch, whose permanence depends on its key-stone and buttresses . . . . when the key-stone crumbles, or the butresses fail, the stones fall to more stable position on the surface of the earth, and in this fall heat is developed. In like manner, when from any cause the atomic clamps of the molecules are displaced, the atoms rush into more stable combinations, and heat is set free as before; the polar attractions of the atoms thus producing effects similar to the familiar phenomena of gravitation" (Cooke's "New Chemistry," 8th edit., p. 358). ". . . in the burning of one pound of hydrogen, sufficient energy was developed to raise a weight of 47,888,400 lbs. to the height of one foot . . . ." (Cooke, *op. cit.*, p. 219).

the entire organism, and have a greater place and power than have the secondary differentiations. (*b*) That in the main, the deviation of the molecular modes and motion of protoplasm, which are the bases of general diseases—cholera, fever, cynanche, herpes, pneumonia, etc., must be of one grand type, and orderly, and in continuity with the primary motions and energy of the evolution of protoplasm. (*c*) That the Form of disease must be as wide, both as to the time involved and as to its cosmic correlations, as are the time and correlations of the evolution of protoplasm itself. (*d*) That the so-far ultimate Forms of the evolution of protoplasm must be in motion, and its varied and correlated modes—heat, etc. These vast and not-yet-read motions we express by the words, "molecular energy." (*e*) 98.4°, though its more immediate cause may be to some degree differentiated, *e.g.*, in oxidation of muscular tissue, in arrested cycloidal rotation of discs, etc., must have source in the activities of the molecular changes of every atom of the protoplasm—both tissues and fluids—of the system. Incessant change must be in process in all tissues, both in the evolution of highly complex organic bodies, and in their devolution—a constant birth and death. Thus the absorption and storing of heat, and its evolution, must be ever going on in every molecule of the organism. The mighty molecular forces, or energies of evolution and devolution, which are ever in operation in protoplasm, must be about balanced; but the cosmic energy becoming life is the greater, resulting in creation and health.

Classification.—The present classification of disease is like to that of language, prior to F. von Schlegel and the comparative philologists: there was a vast array of facts which overwhelmed the mind. Schlegel's "Illuminating Idea" (Coleridge) gave order, unity, continuity, and an ever-expanding path toward more light. The comparative method and the idea of continuity which Schlegel gave to language, have reached all the realms to which thought can be applied, from physics, through all the sciences, and even to the higher mythologies. This method, from Goethe to Darwin, has penetrated biology. It is impossible to hold the faith of cosmic evolution in the vegetable and animal worlds, without, as a "necessary truth," holding that an orderly evolution and continuity must obtain in all disease—in its earliest inception, or the earliest deviation from health—throughout its continuance, and in its decline. Take, for example, the fevers of different latitudes: are we to suppose that the different aspects, courses, and results of fevers, point to a greater difference, or to a greater unity? All analogy teaches us that a great Form or method is common to them all. The periods of intervals during which man does not librate into fever, the pyrexia, the general duration of the disturbance in individuals and in communities, all point to a common Form. Yellow fever, cholera, cynanche tonsillaris, typhoid, typhus, etc., have all had an origin from *chill*, or other altered correlation of environment. That they do not show at all times, implies that the extreme of instability of protoplasm is reached at certain intervals only. Not only is the grander outer aspect and natural history of the great fever group indicative of a common Form; but can it be otherwise than *à priori* true that a vito-chemical and molecular change in protoplasm, albuminoids, etc., of almost identical nature, is common to the group?

If these statements appear too hypothetical, I ask, view ague. (*a*) There are quotidian, tertian, and quartian agues; but not only does this series exist, but there is a very great variety of fevers, called by natives of India, *tup* or *bokar*, which are of ague type, but which it is impossible to classify under either of the three classes named. I have as certainly seen herpes alternate with ague, as neuralgias following ague. Then, again, there are a great many cases of fever which cannot be said to be either distinct remittents or continued. Then, again, there is that fever known as epidemic pneumonia. I have seen an epidemic of a fatal type of bronchial fever. Cholera itself has grades, from a febrile attack, from slight diarrhœa only, from a slight malaise up to the sudden and fatal-blow cases of the earliest stage of some epidemics. Indeed, other diseases at cholera seasons show the choleraic type.[1] (*b*) Then, again, gradation in the outer aspect of phenomena is seen in that epidemics occur which cannot be classed either as pneumonia, or congestion of the lungs, or fever. I cannot but hold the hypothesis that an infinitely delicate difference of the degree of change in the devolutions and modes of protoplasm, is the determining præstage of a fever and pneumonia.

I have seen the *de novo* evolution of typhus,[2] typhoid, whooping-cough, measles, scarlet fever, membranous croup or diphtheria, varied continued fevers, cholera, erysipelas, mumps, small-pox or chicken-pox, cynanche tonsillaris (epidemic), etc. The greater study of these phenomena points to *gradations*, to alliances, and to Forms in common to the so-seemingly-different groups. Must not a basis of classification embrace and rest on a great vito-chemical common form of change in protoplasm, whose delicate differences in degree correlate with the graduated series of disease? Must we not *deductively* seek, by analogy, and by the law of continuity, for this great common Form or order of protoplasmic or albuminoid devolution? We are sure that the changes in protoplasm which make for disease are in absolute continuity with those processes which are ever in action in health.

Another entrance has been made into the nature and Form of the processes of disease by the action of quinine, etc. We know that we can modify the molecular processes which make for disease by a great variety of changes and agents, *e.g.*, ague can be arrested and prevented by quinine, opium, change of place, change of winds, etc. We are thus put on the path or method of the processes; but such path is not opened by one instance only; the grand group of the vegeto-alkaloids, in their varied actions, all show a like power of molecular action and motion. Different as are the therapeutic actions of such remedies as nicotine, strychnine, morphine, etc., yet we can never doubt that their *grand* mode of action is one; their differences of therapeutic action are due to the minor variations of molecular actions and motions. To use an illustration, view for a moment the entire ensemblage of all existing and possible harmonies from Beethoven down to the limited harmonies of the Indian tom-tom; the whole range of such, and, indeed, of the universal harmony and music, are but variations of but one simple physical existence—viz., the vibrations of matter and

[1] It is a bad method to speak of "other diseases showing the choleraic type." For it is the system, the protoplasm, which, at periodic intervals, has allied generic devolutions into poisons or states, which thus become parts of and common to many groups of different diseases. Thus I have seen a bronchial attack assume a choleraic type.

[2] See *Medical Press and Circular*, June 8th, 1870; *Medical Times and Gazette*, January, 1874, September, 1881; and PROVINCIAL MEDICAL JOURNAL, 1886.

waves of fluids.[1] Or again, are not all the infinite movements of the physical cosmos, reducible to the simple laws or Forms of gravitation? Nor can we doubt that the forms and movements and actions of organic life are subject to, and part of, the Form of gravitation.[2] Again, this century has shown that all the "physical forces," heat, light, electricity, etc., are correlated modes of motion.

With such instances of the method of nature, can we doubt for a moment that the action of therapeutic agents is on the molecular motions of protoplasm, and that the differences of action of morphine, nicotine, strychnine, etc., are contained, and minor variations of a grand Form of vital motion: *à fortiori* disease, cholera, etc., are, in their deeper pathology, disturbed inharmonious, yet orderly, molecular motions in protoplasm. We are apt to lose sight of the infinite complexity of process and motion which make the full harmony of life. There is ever present, the grand tendency for the complex, highly differentiated compounds, to revert to more elementary, more chemically stable bodies. Can we wonder that, at periodic intervals, the then-existent protoplasm of a race—survived and correlated to somewhat uniform conditions, say in Bengal—should show a slight and general reversion from its highly differentiated and unstable tensions or conditions? Is it not just to expect that such reversions of the general protoplasm of the race in Bengal, should mainly be constant, but varying to a small degree, and this variation would be expressed by the "sporadic;" and that such instability of protoplasm would, at periodic times, such as the *extremes* of annual heat and cold, and other changes of climate, such as rains, or heat, or winds "out of season," show in a large proportion of individuals over a larger area of protoplasm, and thus the epidemic appears. In Bengal and Hindustan such is the form of cholera.

Further, as we view life as the expression of the survivals and correlations of cosmic motions, and as in disease—*e.g.*, cholera—the motion of every cell-contents, and of every organic fluid within the body must be changed, we have a near explanation of infectivity. The new motion, essential to and part of the disease, is capable of conveying its motion to the molecular modes and motions of other individuals; but in harmonics it is impossible to add certain motions to others—there must be receptivity; there must be, in harmonics, an alliance of method between the old and new motions. And so it is in the more complex motions of protoplasm. The molecular motions of the protoplasm, or in other words, the stability of chemical mode, of some individuals, will not take on the new motion or variation of the disease. We thus approach the Form of infectivity and the Form of resistance to infectivity, by one general hypothesis of molecular motion and their harmonics; or in other words by the higher dynamic chemistry.

Thus a broad view of the action of therapeutic bodies, in their grander and general power, and in their varied and different actions, points us to a great Form of the receptivity of protoplasm to new and changed molecular motions; or viewed chemically, they point us to the grand law of the tendency of organic bodies to revert to more stable bodies with the evolution of heat. The vegeto-alkaloids—strychnine, morphine, nicotine, etc.—are necessarily less differentiated than is animal protoplasm; they are, being vegetable, in earlier stages of the continuity of cosmic evolution; the capacity for them, or for their isomeric forms, to overlap or exist in animal tissue, is implied by the law of orderly cosmic evolution in continuity. We have a right to expect that isomers, or allied molecular motions, to those of strychnine, morphine, etc., should appear in the natural devolutions of protoplasm, and that thus the so-far autogeny of disease, is philosophically and scientifically to be expected.

With the development of higher chemical law, and with wider generalizations in organic chemistry, based on the great Form of continuity, we may fairly expect a great underlying vito-chemical basis of classification in our pathology, and which shall further show the method of continuity in our therapeutics. We are sure that there is no specific difference between carbon and other so-called elements. The properties of the organic are as fully under the forms of continuity and conservation of energy, as are those of other elements. The evolution of cells is as necessitous, with and of carbon and its modes, as is the evolution of water with and of H_2O. The fullest chemistry of carbon, nitrogen, etc., will shew that the reversions or devolutions of protoplasm are necessitous and orderly—are but part of the same curve as is that of their evolution. We see that starch, sugar, etc., are among the earliest products, from the inorganic to the organic, and as alcohol and the vast series of its compound-radicals and varied derivatives follow on in an orderly evolution, so we may fairly seek in their method and series, not only a path of coördinators of protoplasm (*e.g.*, alcohol, aromatics, acids, etc.)—*i.e.*, of therapeutic agents—but we may fairly seek by the same path an early entrance into the method of vito-chemical devolutions of protoplasm. The differentiations of protoplasm seem infinite, but yet we are sure that one great orderly method obtains throughout. The constantly-present influences of environment on protoplasm are but minor parts of the Form of energy becoming life. Not the less, all environment—*i.e.*, all physical and vito-physical existences in their correlations and pan-diffusion—are inseparable parts of such form of vital energy, *e.g.*, part of our protoplasm differentiates to capacity for vision, from the degree of the hydra, which seeks the lighter side of the glass vessel in which it lives, up to the powerful differentiation of vision of the eagle; it thus necessarily follows that the very existence of protoplasm has necessitous relation and dependence on the energy of light and its correlations. In other words, light is one of the cosmic energies which go to create, which is even a *part* of protoplasm; and so it is as to all the other senses; nor can we refuse an equally wide base for 98.4°.

We approach the study of disease:

1. By its outer aspect, as presented to the eye and other senses: our present classification is thus based, and is grandly natural and true; it is parallel to that of languages, prior to the era and idea of F. von Schlegel, and the comparative phylologists.

2. Anatomically and physiologically—or by structure and function—and both structure and function, in disease, viewed in continuity with their order and rates in health.

3. Pathologically—embracing structure and function—changed chemical modes and bodies; bacteriologically, which must be in absolute continuity, both in its cellular

[1] Such is the receptivity of protoplasm, such its capacity for condensed motion, that the seventh nerve and its correlated parts are capable of phonographing the infinite millions of harmonies which may fall on the musician's ear throughout a long life!

[2] See the wonderful shell-like figures produced by the arm attached to a vibrating pendulum.

forms and molecular motions or powers, with the general laws or Forms of normal cell evolution and activities.

4. Chemically—including inorganic, organic, and the correlation and conservation of energy, and all these viewed by the hypothesis of continuity.

5. Pangenetically, as applicable to vision and the senses, to the sexual, to the nerve irritability, or rather to the primitive irritability of protoplasm as persistent through all the after differentiations. The pangenetic view also embraces the great fact, that polarity and energy are not at the poles, but *in* the element. Also it embraces Darwin's hypothetical gemmules; indeed, Faraday's and Darwin's two generalizations are really one, but approached by two paths: Faraday's by the path of the physical energies, and Darwin's by the organic phenomena of buds, fission, etc.

6. Thermo-pangenetically—which will include the fact that heat, and its correlated modes are disturbed—evolved or absorbed—perpetually in every cell, and in every organic fluid. There must be constant life and death in every cell, and in every molecule, heat absorbed and evolved whose survival is 98.4°.[1] The fact of pyrexia being so frequent a phenomena, indicates a great common law or method in the great fever and inflammatory groups of disease. The blood holds gases in solution, O CO_2 N, etc., and thus the activities of life; and the evolving energy are pan-diffused, pangenetic, in every cell. Here, in the disturbance of pan-cellular modes and motions, is a source of diseases—cholera, etc. Here may be laid the præstages of diseases—fevers, febro-inflammations, etc.

7. Therapeutically—therapeutic action must be orderly; we are overwhelmed with the vast detail in every part of the field. When quinine reduces temperature, though we must not exclude the nerve-centre study, yet as nerve-centres are but partial differentiations of pan-thermic potentialities, we have to look more to molecular chemistry, and to the amazing energies which are contained in matter, and which are evolved when it is undergoing changes of mode. It seems fair to hypotheticate that quinine arrests chemical reversion of the highly differentiated protoplasm to more stable bodies, for it arrests the evolution of heat, not only in agues, but in a great variety of other diseases. Quinine may, in such cases, arrest the formation of alkaloids, or of modes or states of protoplasm, which are poisons; but we have to guard the mind against assuming any finality of process—*e.g.*, that strychnine, etc., act as they do, implies a non-harmonious molecular motion. Therapeutic action involves a great Form of molecular motion, whose laws we have to seek in the higher molecular chemistry. The same or allied law would appear in the action of the evolved isomeric poisons of many diseases.

Pyrexia must be in continuity with 98.4°. 98.4° must have cosmic correlations in the cosmic evolution, and involve the conditions of the evolution of the protoplasm itself. In minor circles, its causes may be sought in (*a*) arrest of cycloidal rotation of discs at the capillaries (Woollcombe); (*b*) in chemical process—oxidation—of every particle of protoplasm, since the blood contains O in solution; (*c*) in the oxidation of tissue and blood in the lungs; (*d*) in the evolution of energy—heat—from inter-molecular change. Animal heat is *part* of all life; it is absolutely *part* of all cellulo-chemical bodies; it is latent or absorbed in the actual evolution of life. Heat, in some of its modes or energies, is absorbed and condensed in the evolution of every cell. When the carbonic acid of the atmosphere, and the nitrogen of the soil, are, under the power of the sun, transformed into sugar and starch, etc., heat is condensed and absorbed; and, when further, these plants evolve, under sun energy, to higher products, alkaloids, albuminoids, etc., heat and its modes are yet further condensed and absorbed. The living body must thus be a vast storehouse of heat in its various modes, and of molecular energy and motion. Imagine the potential energy of the nitro-glycerine groups; nitro-glycerine is $C_3 H_5 O_9 N_3$ in which "the molecules have a definite structure by which these atoms, *i.e.*, the non-saturated O atoms, are kept apart" (Cooke, *op. cit.*, p. 250). It is impossible to view the energy of nitro-glycerine without feeling that other compounds of allied chemical molecular composition must have latent potentialities of energy of vast power. Every function and action of every cell is a survival, and has absolute and cosmic correlations. The existence of the vegetable alkaloids, and the evolution of their isomeric molecular motions, where, say, hysterical tetanus happens, are as orderly and as obedient to law, as are the ratios of a falling body. Let us view ague as a type: we see, first, the disturbance of the fundamental irritability of protoplasm as shown by the sense of chill and tremor; secondly, the liberation of heat—hot stage; thirdly, the sub-normal stage of heat.

Few practitioners but must have traced these general courses of symptoms and temperature in measles, scarlet fever, erysipelas, etc. Allowing for what we, in other fields of phenomena, call subsidence, compression, and variation, the course of an ague is typical of all fevers, including cholera.

In the early stages of some cholera outbreaks men die as by a sudden blow. The purging and vomiting are as nothing. A community in India may have been long free from cholera, when a sudden change of weather happening, *e.g.*, to colder wind and rain, to still murky heat and sky, to sudden hot winds out of season, etc.; within a few hours many will die of most malignant cholera. But often before great outbreaks of cholera, a few sporadic cases will show during a week or more. The only hypothesis which seems adequate to explain the phenomena is, that at recurring periods, the protoplasm of the communities has reached a mode of heightened unstable equilibrium. Then, almost any change in its environment and correlations will be the occasion for its devolution or reversion into new vito-chemical bodies, modes, and motions. The infinite delicacy of harmonious molecular motions, and equipoise of correlation, is disturbed; new and inharmonious motions are established, not synchronous or correlated with the then habituated and survived motions and states of the organism. That a few isolated sporadic cases should first show, followed by a sudden outburst, and this again followed by the milder type of cases, in gradually lessening numbers, points to the gradually accruing instability of protoplasm—its sudden fulness of instability—and then the exhaustion of the grander instability as shown by the few and milder-typed later cases. The old observation that, at cholera seasons, many different diseases show choleraic type, is in harmony with the evolution and pan-genetic hypothesis of cholera.

In our rude chemistry, the products of combustion—*i.e.*, the products of molecular motions, can be greatly modified

[1] Professor McKendrick says: *Lancet*, August 18th, 1888, p. 303, Glasgow Address, " . . . . The living body is an aggregate of living particles, each of which breathes in the respiratory medium passing from the blood."

by our methods of procedure; and *à fortiori* the products of molecular change and action, in the highly atomic and unstable bodies of the organism, will vary much under different changes; not the less, generic types of change will obtain throughout the great variety of the different products of both groups. For example, the frequent long hot stage of an ague, and the not-recognised hot stage of a cholera, do not destroy the generic type of the two diseases. Whether we, from a wide point of view, contemplate disease, or pyrexia, or the power of certain cell-products—poisons—in the system, or the action of therapeutic remedies, we are brought face to face with a grand Form of molecular energy and motion, which has become, and is becoming, life, and whose librations and disturbances are involved in the nature of disease.

Look at one of these sudden and collapsed cases of cholera which occur at the early periods of epidemics. I do not disregard the vomiting, diarrhœa, cramps, etc., but are there not greater facts? The greater fact is the aspect of the patient. He lies on his back, his arms and legs straight and rigid, he is cold, sunken in texture, his whole aspect approaches that of a corpse, the vitality of the organism is almost gone; the patient gives the impression that the activities, which go to heat and intertextural movement, are stricken low, and these phenomena pervade every part of the body; the blood does not now normally stimulate the heart; its protoplasm has lost some of its modes of energy, and all other differentiated protoplasm is affected. I can form only one approximative hypothesis—viz., that the inter-molecular motions and equipoise and correlations of protoplasm are disturbed—that a reversion from correlations which are essential to, or are parts of heat and other vital modes and motions has happened. The sudden loss of heat is a sign of a pan-suspended or deflected intermolecular action. The suspended action of such an infinite series of processes must in true continuity of law result in less complex chemical bodies—alkaloids, etc.—whose molecular motions are out of harmony with the survived and correlated motions, *then essential* to life. The secondary fever marks the period of the return to normal states, the exhaustion or combustion of the new bodies, which arose from the primary libration of mode and composition of protoplasm. The sudden collapse, the stillness, the rigidity, coldness, the corpse-like state of typical cholera, impresses one that its pathology lies deep in loss of those intermolecular motions and changes which go to heat, and other modes of vital motion.

We know how transcendantly delicate are the correlations of environment, on which the functions and lives of many plants and animals depend; the human protoplasm must be of equal susceptibility; indeed we all know how great a variety of changes of environment have been followed by cholera. In the main, cholera is an evolution, a temporarily changed mode of molecular motion in protoplasm. But we have indisputable proofs that cholera is sometimes communicated from the sick to healthy attendants, and this fact is explicable in that the the new motions of the protoplasm, as existent in cells, bacilli, organic fluids, and the modes of the organism, in cholera cases, are capable, like the new motions of a yeast cell, when presented to sugar at certain temperatures—*i.e.*, in certain, to it, harmonious motions—of exciting or setting a-going a vast amount of like change or motion in the receptive protoplasm of other organic matter and individuals. The receptivity of the protoplasm of any individual or of any community to the ferment-like action of cholera motions, in those cases where cholera has followed the importation of cases, will be but part of the same great Form of the unstable equilibrium of protoplasm, out of which cholera precipitates *de novo*, from a great variety of shocks and changes. The pollen falls in vain on the stigma except at certain seasons of activity of motion in the ova. The phenomena of parthenogenesis demonstrate that fecundity may be independent of the applied ferment, or spermatazoon or different cell-activity and motion.[1]

We see a somewhat definite proportion of a regiment or district pass into cholera during an epidemic, and thus ask: what are the devolutions or reversions of protoplasm and albuminoids, which we assume to be the conditions, or part of the series of changes, which precipitate cholera? We are sure that such changes must be orderly and according to law; we know that they are ever happening to some degree, for we have the sporadic cholera ever present; we are sure that they are "generic," for cholera is a most varying phenomena, from simple diarrhœa, remittent fever, cholera, fever, cholerine, up to other diseases showing the cholera type. Further, these precipitating conditions of cholera have appeared after a very great variety of changes of environment; cholera has as surely appeared after mere change of place by the individual, or after a shift of wind, etc., as from the infection of bacilli, cells, etc., having the particulate motion or powers of the protoplasm of a cholera case. From all these facts, we conclude that cholera has not a sole specific cause, but that its causes or conditions are generic. Hence we ask the chemist: what are the primary directions of changes and devolution or reversion in protoplasm and albuminoids? Schutzenberger says (On Fermentation, 4th ed., 1886, p. 255): "Among these groups (albuminoid substances), many closely allied species may be placed, which owe their existence and individuality only to certain subtle divergencies of properties, which present to the mind nothing very distinct, such as the manner of forming precipitates with different re-agents." "The soluble ferments, the peptones, are products of the decomposition of albuminoid substances."—(*Op. cit.* p. 257). The complex results and varied products of the splitting up of albuminoids (*op. cit.*, pp. 259, 260, 265, 6) suggest the like result within the system, and harmonise with the phenomena of the so-far autogeny of cholera, and with the fact of its so very varied type, and its so varied and wide alliances. Schutzenberger says (*op. cit.*, p. 254): "So long as the question of the constitution of the immediate principles of animal tissues has not been determined, it will be in vain for physiological chemistry to investigate, by the most careful direct analysis, the different elements of an organ, or of a liquid, whether in a normal or pathological condition; we shall always be stopped by the unknown in the interpretation of the results which have been obtained."

That quinine, arsenic, opium, alcohol, infusion of lemon peel, change of environment, etc., are capable of arresting the conditions which make for ague or other fevers, puts us on the method of prophylaxis. Slight changes of environment have been found to arrest that devolution of protoplasm which is followed by cholera. Broadly viewed, medicine cannot be separated from the highest physics

[1] Darwin says:—"All the forms of reproduction graduate into each other, and agree in their product, for it is impossible to distinguish between organisms produced by buds, from self-division, or from fertilized germs."—(Animals and Plants under Domestication, vol. ii., 1868, p. 383.) Again, Darwin says:—"The female element includes nearly sufficient gemmules of all kinds for independent development.'

and the highest chemistry. These sciences are *part* of cosmic biology, both in health and disease; they are *part* also of therapeutics. The word "infinite" is not too great a measure of the delicacy of correlation and equipoise, on which life, both in health and disease, depends. But if the higher chemistry should demonstrate the series of new devolutions of protoplasm which are associated with diseases, we shall even then not have reached the goal. The mind will ever seek the Form or law of the molecular motion by which morphine, atropine, strychnine, etc., and the autogenetic alkaloids act on the system so differently. And such Form or law, we are sure, must be in continuity with other great Forms in physics and chemistry. Thus we have the powerful method of deduction to aid in the study.

The medical mind, during this generation, has clearly seen that prophylaxis is the main direction for warding off disease, and hence has arisen the great advance of all hygienic measures in what concerns pure air, water, and cleanliness. It is, however, seen that cholera, small-pox, yellow fever, etc., will happen with the most perfect hygienic surroundings. Indeed, yellow fever often appears in those of the finest physique and health. We thus recognise that disease has a deeper base in the capacities and devolutions of protoplasm, and in the Forms of the great biological evolution, which hygiene cannot reach. But the history of human knowledge has often demonstrated that the mind, by a submissive method, and deductively, and by analogy, can grasp the true Form of phenomena long before analysis has demonstrated them. Hence we have strong and just hopes and expectations that we may be able to perceive the true coördinators of protoplasm against its devolution into the modes, motions, or poisons of cholera. An entrance has already been made in this field, in that we know that cholera will evolve after a great variety of *changes*, and will cease after and with certain changes. The study is thus narrowed to the grasping of the essence or Form contained in the *changes*, in relation to the unstable conditions of protoplasm. Such causative *changes* are not confined to outer environment of climate, place, season, etc., but include internal environment, such as the changing an accustomed drinking water, taking a saline aperient, a debauch of food or drink; indeed, an emotion has precipitated the fatal changes in the protoplasm. Observation has shown that a vast variety of *extremes of change* of our habituated climate or outer environment may, in cholera seasons, *i.e.*, at periodic recurrent librations of protoplasm, precipitate the disease. For example, the extremes of the hot season, and the extremes of the cold season (Calcutta); the extremes of heat (May and June), followed by the extreme of rain (July), is followed by the sudden, short, and severe outburst of cholera in August (Lahore)—Lewis and Cuningham, *Practitioner*, April, 1878, p. 309.

In Glasgow, in 1848-9, the highest mortality of the epidemic was in January (Baly's Report, p. 30). In the St. Petersburg epidemic of 1852-3, the highest mortalities were in November (666) and in May (710)—*op. cit.*, p. 31. In the epidemic of cholera in England of 1854, the observations of Mr. Glaisher showed many *extremes* from normal habituated conditions—*e.g.*, "the velocity of the air was less by one half than its average for some time before;" "weak positive electricity;" "no rain;" "a dense mist and stagnant air, with a temperature in excess;" "a high night London temperature, a small daily range, an absence of ozone, and no electricity." "The three epidemics (1832, 1849, 1854) were attended with a particular state of atmosphere, characterised by a prevalent mist, thin in high places, dense in low." "The barometer was remarkably high." "The night temperatures were high, with small diurnal range, . . . a deficiency of electricity, . . . a total absence of ozone." In 1832, 1849, 1854, "the stagnant atmosphere was prevalent during the time of cholera. . . ." (Appendix to Report of the Committee for Scientific Enquiries in relation to the Cholera Epidemic of 1854—Blue Book, pp. 116, 117).

Here we see that there existed *extremes* of many of the habituated external correlations under which the protoplasm of the communities had evolved. The duration of life, in species and genera, is not a fixed quantity. The protoplasm of different species and genera exists, as individual units, for periods varying in all degrees, from one day in the myriad tropical ephemera to the centuries of the tortoise. Is it not to be expected that the protoplasm of a community should show periodic tendencies to libraation? Assuming such to be the case, we see, then, that the extremes of vito-physical external environment, which I have quoted above, may justly be held as capable of upsetting the essential correlations of an unstable vito-chemical protoplasm.

The history of medical opinion on cholera will, I think, show that we have too often insisted on one or more associated conditions, as potential causes of cholera. It would rather seem that at periodic intervals almost *any extreme*, *any departure* from habituated, and then correlated, mode of environment, is capable of precipitating the poisons or inharmonious motions of cholera in protoplasm.

But in India, where cholera is endemic—*i.e.*, where the protoplasm tends to modes whose results are cholera—the *de novo* evolution of cholera has often followed a great variety of sudden changes—*e.g.*, sudden dust storms (Dr. W. Wakefield, *Lancet*, September 9th, 1884, p. 257). "Rain holding off during the monsoon, cloudy and dull weather, with occasional rain in the hot season, are both, in my experience, conditions under which cholera is likely to make its appearance" (Surgeon-Major Sargeant, *Lancet*, August 11th, 1885, p. 57). Sudden cold rains, sudden heats, still murky sky, out-of-season rains, heats, etc., mere changes of place, etc., have all been followed by the *de novo* evolution of cholera in India. I have already referred to the *de novo* evolution of cholera from changes in food, drinking water, etc., also from mental emotion or shock.

I have, I believe, quoted from the history of cholera in England and India, a sufficiently wide class of instances to convince us that the major Form of cholera cannot be in any one or more external condition, but rather it would appear that the major Form must be sought in the capacities and devolutions of protoplasm.

Thus the methods of observation and analogy go along in the enquiry, parallel with the researches of the chemist on the devolutions of the albuminoids, and parallel with the higher developments of physical science in all that relates to the correlation of the physical energies, which are not only essential conditions of, but parts even, of life. It is impossible to draw a line between chemical and cellular changes; the two are parts of one series. The approximative generalisations I have advanced on the devolution of protoplasm into new modes, motions, and poisons, by means of *changes*, and the coördination of protoplasm from devolution by means of *changes*, are equally applicable to chemical and to the cellular or bacilli theories.

But we are, beyond all else, impressed with the extreme

delicacy of those changes which interfere with the modes of correlation on which life depends; and hence we know how small, yet all-potential, may be the true coördinators of health.

We know of cholera outbreaks ceasing, with very varied changes, as of season, winds, rain, place, etc. The actual physical differences involved in such changes, may be very small, but they are all-powerful for the stable coördination of protoplasm—*e.g.*, in the Kurrachee epidemic of 1846, the wind, which had been "south-west, veered to the north-east, there was a fresh breeze, and the pestilence begun to decline" (*M.C.R.*, April, 1856, p. 301). Dr. French, H.M. 49th Regiment, said: "It has frequently come under my observation in India, that violent storms of wind and rain have, for a time, either entirely arrested or greatly mitigated all the symptoms of the disease" (*op. cit.* 302). Surgeon-Major Sargeant says: ". . . . at Lingusagar, in 1869, cholera ceased with the advent of a high and continuous wind; at Aurumgabad, in 1873, the same result followed the recommencement of rain; and in 1883, in the neighbourhood of Hingoli, cholera disappeared at the same time that the atmosphere cleared and became bright and cheerful" (*Lancet*, July 11th, 1885, p. 57). Mr. Scot reports that "cholera (in Madras) would cease on this appearance of the sky (dull leaden-coloured suffusion obscuring the sun. . . . and attended with a certain chilly feel in the air) breaking up, especially if ending in a storm" (*M.C.R.*, April, 1856, p. 303). Surgeon-Major Welch says: "that when the troops suffered cholera in Malta, the disease ceased when the men were removed but a hundred yards (*B.M.J.*, December 1st, 1883).

We might greatly extend the number of instances of cholera ceasing, with changed environment. It is significant to observe that sudden changes to wind and rain, which have so often precipitated cholera in India, have also often stopped its evolution. But these seemingly opposing facts are in perfect harmony, if we view the major Form of cholera as a devolution on changed molecular mode of protoplasm. The unstable equipoise of protoplasm, may, at recurrent periods, be precipitated into these modes and poisons, which lead to cholera, by almost any change of environment, including the change to wind and rain; but at a later stage of the recurrent instability of the protoplasm of any community, when the poison evolved is less toxic, when the main libration of the protoplasm is much exhausted, it is reasonable to expect that the rain and wind would be conservative of the normal modes of protoplasm. We know that the later stages of the cholera outbursts are less severe in type than are the early stages, and we say, therefore, that then the devolutions of protoplasm are less in degree. We see, at any rate, how exquisitely delicate in amount may be the precipitating conditions of cholera, and not less exquisitely delicate are the conditions capable of arresting the devolutions of protoplasm into cholera.

It was on these analogies, and, in part, deductively, that many years ago I ventured to suggest to the Governments of India that, when cholera showed in a regiment, jail, etc., those *not visibly affected* should be hypodermically injected with a solution of quinine and arsenic in an acid, or by some one of the aromatic class. The idea was that we might thus change that special state of unstable equipoise of protoplasm, which so readily, at such and recurrent times, tended to revert into those motions and poisons whose results are cholera. We may be sure that the apt and effectual coördinator against such devolution of protoplasm will be very small in amount, and that it will be obedient to the laws or forms of vito-chemical continuity.

Bacon says: "But be assured that the prolongation of life is a work of labour and difficulty, and consisting of a great number of remedies, and these aptly connected one with another. For let no man be so dull as to believe that a thing which has never yet been done can be done now, except by means yet unattempted." ("De Augmentis," 4th Book.)

ON OSTEITIS DEFORMANS, OR SENILE PSEUDO-RACHITISM.[1]

By S. Pozzi, M.D.,
Surgeon to the Lourcine.

Continued from p. 90.

The maximum of the projection on the anterior face of the tibia reached six to seven centimètres, below the edge of the condyles. Deformity of the external condyle; its anterior border appeared destroyed; but this appearance might be produced by the osseous tumefaction situated above; its external border a little salient; tibia sensibly larger at the top of the curvature; to the hand it was hot, sensitive to pressure; no souffle or pulsation. She did not suffer much, but felt that each day the leg became weaker; and as she was already notably of *embonpoint*, walking became more difficult, and the projection increased (iodide of potassium internally; mercurial friction; apparatus).

December 22nd, 1872.—The projection of the bone a little increased. In spite of apparatus, persistence of pain on touch.

February 15th, 1873.—General augmentation of the column of the tibia; the external condyle and the anterior tuberosity of the tibia more prominent than on the healthy side; hypertrophy already manifest.

May 5th.—Prominence of curvature lowered. For four years the patient remained in almost the same state. She found herself relieved by the apparatus, which had to be modified several times on account of progressive obesity. At the same time gouty phenomena accentuated; digital nodosities more marked; uric acid and urates in the urine; digestive trouble. Cure at Vichy. I saw the patient again on April 7th, 1877, finding her in the following state:—The increase in bone through its length is much more marked—two centimètres. As regards the thickness of the tibia, it appeared almost double that of the tibia on the sound side; the bone is rugous. The form of the curvature is changed; it is anterior, but the salient point is still lowered. In proportion as the bone is consolidated above, it is thinned below and weakened. Casts taken at various intervals since 1877 allow for this lowering in the prominence, which commenced in 1873. As regards heat, it diminished at the projection where it was previously sensible, and had always its maximum at the top of the most salient point.

On the first of May the state of the tibia was as follows: The internal condyle appeared atrophied, and the external hypertrophied; the condyles of the femur appeared also a little deformed, but the *embonpoint* of the patient did not allow us to be precise on this point. In measuring the

[1] A paper read at a French Congress on Surgery.

length of the tibia at different points of the superior extremity to the malleoli, the following differences were found: From the highest point of the tuberosity of the tibia to the internal malleolus on the healthy side, 330 millimètres; on the diseased side, 350. From the external condyle to the external malleolus—healthy side, 380 millimètres; diseased, 350. From the internal condyle to the internal malleolus—healthy side, 330 millimètres; diseased side, 340. The patient remained in a stationary condition since 1880. The projection is always the seat of a little heat. The patient walks with apparatus, but she becomes more and more incommoded by her *embonpoint.*

Observation 3 (communicated by Professor Ollier under the following title):—*Local Osteomalacia of the Left Tibia in a Woman, seventy-six years—Anterio-Posterior Curvature of the Tibia.*—M. V. N——, seventy-six; no children. Habitual health good; no sign of syphilis; no rachitism in infancy; no fracture; no violent traumatism. About four or five years before she had vague and feeble pains in the left leg; no nocturnal pain. The pain is always diurnal, making itself felt after walking at the end of the day. Rest always calmed it. Chronic rheumatism; digital nodosities; urine nòt analysed. The tibia is curved forward; no brusque angular curvature; the maximum of the projecture is a little below the inferior quarter. At the top of the projecture there is heat and pain on pressure. Complete freedom from pain in repose. Same distance between the condyloid borders and the malleoli on both sides. This patient not wishing to use the apparatus advised, the curvature increased little by little. The pains became stronger, the bone sensibly thicker, but without any tumour. The patient lost sight of since 1876.

These three observations, without offering a complete tableaux of the osseous malady of Paget, suffice to give us an idea of it. Let us here review the principal traits. This affection, generally chronic, begins in advanced age; rarely at the middle period of life. There is only one case known where the disease commenced at twenty-eight years; it is the seventh mentioned in Paget's second memoir (*Med. Chirur. Trans.*, 1882, p. 234). It has an insidious progress, and does not alter the general health; it only reveals itself by a progressive and symmetrical deformity of the skeleton, and especially of the long bones. The lower members are ordinarily first attacked. Treves remarked (*Brit. Med. Jour.*, 1882, p. 1155) that in women the bones of the forearm always suffer, this not being the case in men. This rule is evidently too absolute. The two cases of M. Ollier do not reveal any deformity in the arms of the two women he had under observation. The cranium is often deformed, and considerably enlarged, though there was nothing of this in our three cases. Vertebral column may also be bent, and the pelvis enlarged; the clavicles are often attacked. The most characteristic feature in most of the patients, and in ours in particular, is the augmentation of the curvature of the femur, and the bending of the tibias. It is not accompanied by any weakness in the resistance of the bone. In the initial period pain is often observed taken by the patients for rheumatism or neuralgia; as also an elevation of local temperature, very marked in certain cases, as in those of Professor Ollier. No fever.

The attitude of the patient at the last stage of the disease has something striking and veritably characteristic about it. The sinking of the lower members, and of the vertebral column diminishes the height, and provokes a relative lengthening of the arms which appears excessive. The hesitating walk, the rounded shoulders, the head projected in advance, the prominent abdomen, the legs too straddled, and the knees slightly bent, give to the walk of the subject a resemblance to that of the large anthropomorphic apes. Add to that the hideous character of the cranium often enlarged and bossed, and the aspect of the patient, we have a good idea of the type which Paget has described in a manner not to be forgotten.

If the clinical syndroma is definitely fixed, assuring to this malady a distinct place, we must confess the same cannot be said of the pathological anatomy and the etiology. The chief anatomical facts we possess rest on an autopsy made by Butlin on one of Paget's patients. They are as follows:—No alteration of periosteum or of medullary tissue; thickening of the compact substance of the bone, apparently due to the addition of peripheric lamellae, and having the appearance of hard, porous, or finely reticulated pieces of beautiful coral. In places, islets of dense substance, pale, but as hard as a brick. At the top of the epiphysis it would seem that the spongy tissue was replaced by compact tissue. Under the microscope we notice the diminution of the number of the Haversian system, and dilatation of the canals of Havers, which are filled by a granular, amorphous substance, and round and oval cells resembling leucocytes. The presence of new bone is distinctly seen under the periosteum of the tibia. Recently, several specimens of osteitis deformans have been presented to the Pathological Society of London, by Simcock and Goodhart, the former pointing out the great vascularity of the altered bone, and the state of imperfect organisation of the new osseous substance. In his idea the first phenomenon is absorption of osseous tissue, which is followed by a compensatory new formation, forming a kind of interstitial callus.

Chemical analysis did not reveal anything notable to Dr. Russell, to whom Paget had submitted his specimens. In some the lesions have nothing characteristic, seeming to be allied to chronic osteitis. All that we can deduct is that the disease differs anatomically as well as clinically from osteo malacia and rachitism. The etiology is also vague. The influence of syphilis is notoriously nil; is it so with a cancerous diathesis, or at least a neoplastic diathesis? Sir James Paget has seen cancer three times in his first five patients. Goodhart has noticed once a fibroma of the uterus. Steven Paget, in one patient, a pigmented tumour of the groin; in another, a molluscum. Disease of the heart has been observed several times. But may not these be simple coincidences? We must not forget the advanced age of the subjects who suffer from osteo deformans, and the frequency of cancer and disease of the heart in old people. Gout appeared to have pathological importance much more pronounced, being noticed in a number of observations either in the patients themselves or in their ancestors. As regards rachitis, I have only found one observation where it is noticed in the children or the patient. This relates to a woman who had had two miscarriages and twelve children, many of whom were attacked with rachitis. Scrofula is not mentioned as a cause by any author as far as I know, but I must insist upon its evident existence in the patient under my care. The osteitis of the finger with osseous and synovial fungosities clearly establish this diathesis. It is striking to see its tardy appearance at the same time as the lesions of osteitis deformans. However that may be, the nature of the affection remains very obscure. In the opinion of Paget

we have to deal veritably with a new disease. In proof of this he notes the absence of any old description of it, and the absence of any pathological specimens in the museums. The pages in which the eminent surgeon expresses his ideas on its mode of origin, due to a sort of morbid transformism, are, so to say, buried in an address—the Bradshaw lecture—delivered at an official meeting of the Royal College of Surgeons, December 13th, 1882. I cannot do better than give a rapid analysis of this passage, as it is little known in this country. "There seems to be evidence enough that new diseases are in progress of evolution. Good evidence of this kind is to be found, I believe, in the peculiar joint disease discovered by M. Charcot, in association with locomotor ataxy, and in the disease of bones, to which I have given the name of osteitis deformans. Neither of these, I believe, was described till within the last few years. In twenty-six years I have seen twelve marked cases of osteitis deformans, and about as many in which it was only partially evident. In the last six of these years I have seen seven of these cases, and others have been published, and yet I cannot find evidence that the disease was ever seen by any of those who had a practice like my own. Brodie and Stanley had seen no case but that which I showed them nearly twenty-years ago in the patient from whom these specimens were taken. I cannot find an old specimen in our museums, or a representation of one in any book of plates. Hunter, Howship, Langstaff, Liston, Cooper, and Stanley collected not merely illustrations of diseases well known to them, but whatever was curious. They would have looked on these bones as gems."

CLOTHING.

By Francis Vacher, F.R.C.S.,

medical officer of health for birkenhead.

The philospher of Weissnichtwo, who discourses with so much humour and pathos on *die Kleider, ihr Werden und Wirken*, defines clothing as "the vestural tissue which man's soul wears as its outmost wrappage and overall, wherein his whole other tissues are included and screened, his whole faculties work, his whole self lives, moves, and has its being." This, to the reflective mind, is no inadequate definition, and taken seriously, claims for the study of clothing a higher place than it has even yet received. Doubtless, it is true that thinkers are not so altogether heedless of the matter as they were half a century ago, when the sentence quoted was written. Still, if the body gain importance and consideration as being the vestment of the soul, what attention is not due to the clothes encasing and protecting the vestment, on the fitness and adjustment of which much of the efficient work of soul and body depends! One might almost say that of late dress has become rather a popular subject. Certainly it has been much discussed from an art point of view and from a hygienic point of view, and by rival schools of self-styled dress-reformers, whose main aim appears to be to effect such a change in female costume as may give the wearer increased ease and comfort. The art critics, when they began their attacks, said that dress was never more ugly in form, colour, or material, and the change their teaching has effected in the last decade or two, more especially in the dress of children, is a radical and beautiful change, for which they deserve full credit. The sanitary improvers of dress have been chiefly occupied in running a tilt at corsets, and tight, high-heeled boots, and also advocated the more general use of flannel underclothing; but though they have not been wanting in courage, it can hardly be said they have met with the success they merit. As for the dress-reformers, they joined in the attack on stays and Paris boots, protested against a considerable weight of clothes being suspended from the waist, and proposed dividing the skirt. Up to the present no great results have crowned their efforts, and even among those who approve their advice few follow it.

Are there not, then, instructors enough in respect of clothing—artists to show what is beautiful, experts to decide what is healthy, and enthusiastic emancipators to lead the way to freedom and comfort? What more can be needed? My answer is, all that is wanted is a guide to the guides—a plain, common-sense statement of principles, and brief general indications as to how to apply these principles in the clothing of men, women, and children.

PRINCIPLES.

Wearing apparel is primarily intended for warmth, protection, and decency—it may be used also for ornament, and to conceal defects of form or age, scars, etc. The ornament should not interfere with the usefulness of the dress, and should not be expressed in meaningless buttons and bows, mere contrivances for gathering dirt. For concealment of defects loose-fitting dresses will do much, and a little padding is allowable. The main object being to protect and cover the body, to assist it to maintain an equable temperature, the question is—what materials and make of dress will best secure this? In respect of *material*, the requisites are that—

(*a*) *It should be a bad conductor of heat.*—As the body is always losing heat by radiation, by evaporation of sweat, by conduction and by convection, and the bodily temperature is 98.5° F., so much above the temperature of the air, this is of first importance. Now there is no doubt that materials made of wool take a first rank as non-conductors. The best materials, therefore, are woven wool, knitted wool, flannel, woollen cloth, etc.

(*b*) *It should be pervious to air.*—This is very essential, and leads to the selection of the same materials. Taking the quantity of air passing through flannel and loose woollen fabrics at ten, the quantity passing through linen is about six, and the quantity passing through chamois leather and silk is respectively five and four. Thus silken under-vests and chamois chest-protectors are distinctly contra-indicated. Where there is no free passage for air, there can be no ready outlet for cutaneous perspiration, and the functions of the skin will be interfered with. Well-ventilated clothes are the warmest and most comfortable, while unventilated clothes are as insanitary as unventilated rooms.

(*c*) *It should not be harsh or irritating.*—This is a negative requirement, but it is well that it should be stated, as a great authority (Dr. Jaeger) asserts that clothing should gently titillate and rub the skin, in order to maintain a constant and ample blood supply, and assists the self-cleansing powers of the skin—the shedding of the outer cuticle. It is doubtful if this be sound teaching. Ordinarily, woollen underclothing is not irritating, even in a slight degree, but those who find it so will do well to make trial of a fabric containing some admixture of cotton or silk. Persisting in the use of underclothing which irritates the skin, however slightly, is unwise.

(*d*) *It should wash well and wear well.*—The better the fabric the better it will wash and wear. Poor materials made

of short-fibre wool, or shoddy, and artificially weighted, will neither wash nor wear, and would be dear even if given away. One of the main objections to poor material is that it shrinks, or "thins out" so much in washing, that it is rarely washed; and unwashed underclothing is not properly pervious to air, and conducts away the heat.

(*e*) *It should be suited to the season, and climate, and the age and occupation of the wearer.*—Little need be said under this head. Experience teaches everyone that in our English climate light clothes should give place to winter ones in September, and that those who are careful of their health

"Ne'er cast a clout
Till May is out."

Experience also teaches that one needs warmer clothing in a dry climate than in a moist one—*e.g.*, more in a dry east wind than in a moist west wind, even though the temperature of the east wind be no colder. It is as true that the very young and the aged, and those following sedentary occupations, are easily affected by slight changes in the temperature and moisture of the air, and should be specially warmly clad. The colour of dress material should also be suited to the season and climate, that is, the colour of the material which is worn externally. Putting the capacity of white to absorb heat at 10, the capacity of yellow, green, and blue are respectively 13, 16, and 20. Generally speaking, the darker the colour the more heat it absorbs; therefore white and light colours are best fitted for summer and warm climates. This brings me to the next requisite, that

(*f*) *If dyed, the colour should be innocuous and fairly fast.*—It is a good rule that all clothes coming next the skin should be either white, or unbleached, or gray. Jerseys and drawers dyed "art" browns and greens, and Turkey red, are common and often worn with impunity. Occasionally, however, they cause irritation of the skin, and they should not be recommended. It is of more importance to warn people against a series of dye-stuffs derived from aniline, all of which are distinctly injurious. These, under the names mauve, roseine, fuchsine, magenta, chrysaniline, etc., were, a short time since, much used in dying gentlemen's socks. It was found that wearing such socks was liable to produce local inflammation and eruptions of the skin. For economic reasons it is desirable that the colour of a dyed fabric should be fast; it is desirable also for cleanliness' sake, as a coloured garment that will not bear washing will go unwashed. Occasionally muslins and other similar light fabrics owe their tints to body colours—poisonous preparations of lead, arsenic, and copper, which are readily dislodged in fine particles, and may be carried into the lungs. Finally, a caution should be given against dyes which burn or rot the textile dyed.

(*g*) *It should be strong, and as light as practicable.*—It is obvious that if a material is not strong of its kind it is owing to some defect—it is a shoddy, or has been damaged by damp, or weakened by a caustic dye. Strength is, therefore, often a test of quality. Lightness is also sometimes a test of quality, for inferior goods may be artificially weighted with glue, starch, size, plaster, or clay. I should say that *ceteris paribus* the lighter the fabric the better; that is, if a person be sufficiently warmly clad, the clothing is the best which burdens him with only the minimum of weight.

In respect of *make*, the requirements as to clothing are that

(*a*) *It should cover the whole surface of the body, head and hands excepted.*—This is a simple rule which no sensible person would object to, yet it is not followed. Scotchmen, who dress in the garb of old Gaul, disobey it, and so do ladies who appear in low dresses with V-shaped incisions down the back. The rule is also set at naught by mothers whose humour it is to send their children to walk and play bare at the knees, or bare at the arms. The hypothesis that children's limbs are thus hardened is wholly unsupported by facts. Of the men, women, and children who are exposed as regards knees, arms, and shoulders, some are crippled—some die. The uninjured are strong in that they survive the treatment, not because of it.

(*b*) *It should exert no pressure on any part of the body, and should allow absolute freedom of movement.*—The pressure which is most injurious to the body is undoubtedly that effected by the corset or stays. It narrows the thorax, interfering with the action of the lungs and heart, and displaces and compresses the stomach and liver. But the waist is not the only part of the body systematically constricted by modern dress. The tight Paris boot is as bad in its way as the tight corset, for it cramps the foot, displaces the toes, injures the arch of the sole, and produces bunions and corns. Of late, too, very tight sleeves have been in fashion; sleeves which do not give a lady's arms full play. Also tight skirts, like a single trouser, which hamper the wearer in walking. Garters also come under the description of clothes exerting an undue pressure, and so do tight kid gloves.

(*c*) *It's weight should be properly distributed.*—A glance at the human skeleton will show that there is a strong bone support at the shoulders and at the pelvis. The common defect in male attire is that it is so arranged that nearly all the weight has to be borne by the shoulders; the common defect in female attire is that the weight of the lower garments is thrown on the waist, instead of on the pelvis.

(*d*) *It should be sufficiently short to prevent it from trailing in the dust.*—The train, primarily, was an in-door dress-appendage, designed to give grace and dignity to the wearer, and it would not be fair to say that in this it altogether fails. But ladies were not content with wearing trains in-doors only, the skirts of walking dresses were made to a similar pattern, and the difficulty was got over by making the train into a tail, which could be picked up and carried. Even this form of dress was only dirty by accident, that is, what is carried or hooked up is apt to be occasionally dropped or to come unhooked. However, the humble imitators of ladies, parlour maids, and shop girls, copied the long trailing walking-dress, without copying the arrangement for carrying the tail, and thus it is that gay gowns are seen literally "sweeping the streets." If ladies have not themselves offended gravely, they have been the cause of others offending. The only safe rule to make is that no part of any skirt intended for out-door wear should be long enough to touch the ground.

(*e*) *It should be arranged with due reference to comfort and convenience.*—Comfort and convenience are of first importance in dress, though fashion ignore them, and fashion's votaries make willing sacrifice of them. They are of infinitely more importance than mere prettiness. Indeed, they almost imply suitableness and appropriateness, and are generally safe guides to the individual in selecting. A dress which is uncomfortable and inconvenient will not be healthy, becoming, or artistic. The old practice of making dresses to button down the back is not usual now, but any form of fastening necessitating the use of a dresser is equally unsatisfactory.

(*f*) *It should not be distended with hoops or improvers, or stiffened with steel, whalebone, or wood.*—The farthingale of our great grandmothers, and the crinoline of our own time, now only exist in a modified form as the dress-improver. Is there anything to be said as an excuse for this? What is its use? It has been the fashion to put such a weight of stuff in the back of a skirt that the heat and pressure have become intolerable, and the object of the improver appears to be to afford some relief. Doubtless relief is given, but there would be no need of it if the dress were not weighted with superfluous stuff. Those who use the modern improver will surely not claim for it beauty or grace. See the illustration, an exact copy from a current fashion print. Could

Fig. 1.

anything be uglier? So-called "breast improvers" there is some excuse for, when they are merely used to cover a distinct deficiency, or the wasting due to age. Stiffeners of steel and other material are not used for corsets only, but also in dress bodies and skirts. There is no necessity for them, nor any good excuse. They are as out of place in a woman's dress as they would be in a man's.

(*g*) *It should be reasonably simple, and easily put on and off, and not in excess of what may be sufficient for warmth and protection.*—Clothing made to lace or button down the back, or with hooks and eyes in this position, is objectionable. Not so long ago it was a common practice to make young girls' dresses in this way, so that they could not be fastened by the wearer. Even more objectionable are plaits stitched down, and flounces, and knots, and useless buttons, which are so many contrivances for collecting dust. Indeed, all this is so obvious it goes without saying.

Having thus concisely noted what I take to be the principles which should be followed in selecting material and prescribing the form of wearing apparel, I pass on to the practical part of my subject—the application of the principles set forth. This will be best considered under three heads.

Clothing of Men.

As a general rule the dress of men is more in conformity to hygienic requirements than the dress of women. Still, in some matters, there is abundant room for improvement. First, the boots ordinarily worn by men are more or less pointed at the toes, and too narrow throughout. The result of wearing such defective boots will be seen on reference to the cut (fig. 2), which shows the sole of the natural foot, by

Fig. 2.

the side of the sole of the foot of an adult long accustomed to the use of tight boots of the conventional shape. The skin of the sole is compressed into folds, which may become fissures exceedingly difficult to heal; the second toe (or sometimes the third or fourth) is displaced upwards, and the first metatarsal bone is displaced sideways. The pressure of the upper leather on the proximal end of the displaced bone may cause a bunion, while the pressure on the toes is usually sufficient to produce corns. I am of opinion, also, that this pressure of the upper leather, especially if the boot be too short, is the main cause of ingrowing of the great toe's nail. Square boots, sometimes recommended, made to fit either foot, right or left, really fit neither, and cannot be satisfactory. What then is the proper form for a model boot? I would say that it should be the shape of the natural foot, elastic especially at the waist, large enough to allow for expansion of the foot in walking, and that the terminal margin of the sole should be a curved line corresponding to the curve formed by the toe-ends. Except where the deformity is very great, a foot properly clothed will, in great part, recover itself. Boots should be high enough to reach, at least, an inch above the ankles, and should fasten with either laces or buttons. When practicable, boots should be made to order, as there is no constant ratio between the height of instep and length of foot, or between length and breadth. The socks should be of merino or light woollen material, and they are certainly the better for being digitated, each toe being thus specially provided for, and clothed all round as each finger is in an ordinary glove. The drawers and jersey should also be of light woollen stuff, made to fit the body, but not so closely that the fabric is on the stretch. The jersey should reach from the vertebra prominens to the coccyx, and should have long sleeves; the drawers at the top of the band should be a little above the crest of the ilium, and should overlap the

socks two or three inches. What may be called the first layer of clothes should be undyed. Socks without dye are, however, difficult to procure.

I should not have thought it necessary to warn men against using stays, but for the information conveyed in a price list which recently came into my hands. The list is issued by a well-known London firm, styling themselves *artistes en corsets*, and in it I find that in consequence of the increased demand for corsets by gentlemen, "we have been induced to give this department our special attention, and we feel sure that we shall be able to meet thoroughly and efficiently a want that, up to the present time, has been neglected;" and then follow instructions for self-measurement, the whole being embellished with a picture of a handsome man, with a moustache, wearing stays. Of course stays are every bit as objectionable for men as for women. Indeed, everything that constricts the abdomen or thorax, it matters little under what name, is injurious. The broad belts, fastening with straps and buckles, commonly worn by artisans, runners, and hunting men, are almost as bad as stays, weakening the abdominal muscles, and assisting in the production of rupture.

If the underclothing be sufficiently warm, there can be no possible objection to the use of linen shirts. Dr. Jaeger's word has gone forth against them, and many accept his ruling, and condemn them. But the comfortable white shirt will survive stronger attacks than have hitherto been made on it. The neck opening should be amply large, with collar attached. Shirts should be made to measure, like cloth clothes, and may have any pattern of collar desired. Plain turned-down collars are the best, and close-fitting high "dog" collars the very worst. Shirts with collars attached are infinitely more agreeable to wear, and there is this advantage that they are certain to be changed with sufficient frequency. Working men doubtless will find flannel shirts more convenient, and such shirts are best fitted for boating, hunting and out-door games. They should be made with turned-down flannel collars. Linen or paper cuffs and fronts and collars masking woollen shirts are neither beautiful nor useful. As for collars of cellulose or enamelled steel, they are most of all objectionable.

It is scarcely beyond the truth to say that men have attained to something near perfection as regards cloth clothes. What could be better, from the point of view of healthiness and convenience, than the modern morning dress? the trousers neither too tight nor too full, the waistcoat buttoning high up, and a coat fitting the body exactly, and buttoning down over the waistcoat. When this coat is changed for a frock coat, the dress is still as nearly perfect as possible. Of course, if the morning coat and frock coat are left open, they flap about, and let in the cold air under the waistcoat to the abdomen and loins. However, if people will not wear their clothes as they are made to be worn, it is not the fault of the clothes if they catch cold.

One cannot speak as highly of evening dress, for it is a long way from perfection. Still, most men look better in it than they do in anything else. It is popular, and has withstood many attempts to alter it. The reformer will waste his time in advocating a radical change, and he will do better to make suggestions for the correction of hygienic defects. What are the defects of men's evening dress? First, the material is invariably too thin. This fault is readily amended by a simple flannel lining, which may be added to any suit without interfering with the fit of the clothes, or the freedom of movement and comfort of the wearer. Secondly, the very low waistcoat leaves the chest covered by the jersey and shirt-front only. This is remedied by wearing a large "chest protector" over the jersey—that is two layers of thick flannel at least three inches broader and longer than the waistcoat opening. Wearing a chest-protector next the skin, made of wash-leather, etc., which gets very foul, is a practice justly condemned; but there can be no objection to a double layer of flannel immediately under the shirt-front. In the third place, dress boots are generally made so tight that only thin silk or cotton socks can be worn under them. A very slight increase in the size of boots will make them large enough to go on over merino socks. Having the boots well stretched may be all that is needed. It has also been said that the light muslin tie which replaces the silk scarf of morning dress, renders the wearer specially likely to catch cold. If this be so, the white tie can be made heavier by folding a strip of flannel within it.

As regards great-coats for ordinary wear the best pattern is that known as the "Chesterfield." It is neither too tight nor too loose, and being about the length of a frock-coat, is comfortable for walking in. For driving, there is nothing to equal a stout "Ulster." For evening wear, over a dress suit, I recommend the "Inverness" cape.

There is no use writing anything condemnatory of the silk hat. Whatever be written it will still be worn for some years to come. It is not such a bad covering for the head if it be light and ventilated and fit well. In choosing a hard felt hat, the same requirements should be insisted on. I incline to think that the soft felt hat (commonly affected by clergymen) comes nearer perfection than any other hat I have had experience of. It is cool and light, and keeps the sun out of the eyes; does not get out of shape, is most portable, and uninjured by rain.

Little requires to be said about working men. Their working clothes are usually warm and durable; their waistcoats are high, and they wear stout neckties. The belt so commonly worn round the abdomen I have already referred to—anything of the kind tightly fastened is most objectionable. Workmen, too, have a habit of strapping up their trousers to keep them out of the dirt. The straps are worn below the knees, and are, of course, as injurious as garters in the same position. For men who work in their coats, a tunic, made like a shooting tunic, is better than the open coat. All engaged in occupations which foul the clothes, should use overalls.

CLOTHING OF WOMEN.

In discussing men's clothing, the boots were first considered. The same order may be followed here. Women's boots have all the defects of men's boots; they are pointed at the toes, too narrow throughout, and too tight, besides which they have the additional defect of being made with heels which are too high and occupy a wrong position. Thus the woman's foot is injured, not merely by compression and having the toes jammed together, but by being placed in a position which resembles that of *talipes equinus—vide* Fig. 3, showing a foot in a modern French boot. The wearer of such a boot perforce walks on the ball of the foot; she is constantly in the uncomfortable position of a person descending a steep incline. Nay, worse than this, for the heel of the boot not being under the heel but under the

arch of the foot, the arch is weakened thereby, and may yield, producing the deformity known as flat foot. Then, the balance of the body being difficult to maintain, there is unsteadiness of gait, and excessive strain is put upon the ankles. It follows that the woman's walking power is much diminished, and she probably walks as little as possible; thus many of the evils of want of sufficient exercise may be traced to high-heeled boots. It may be remarked also that

Fig. 3.

such boots are likely to catch in any slight projection, and throw the wearer down, perhaps breaking a limb or causing a fatal injury. As there is no anatomical difference between the foot of men and women, all that is necessary in men's boots is equally necessary in women's. However, it seems specially needful to impress upon women to see that their boot soles are broad enough and thick enough.

It is well to wear woollen garments next the skin. The stoutness or fineness may be regulated to suit the wearer and the season. One advantage of having the stockings digitated, will be that the wearing of light pointed-toed boots will be rendered impossible. Stockings may be kept up by suspenders, but there is no harm in gartering them above the knees, as the tendons on either side guard the vessels from pressure. Woollen clothing covering the body from the neck to below the knees, and with sleeves reaching nearly to the wrists, may be obtained all in one piece (resembling the male bathing dress used in France); but there is no special advantage in this, and the underclothing is as good in every way in two pieces as when combined. As the chest and abdomen require more warm clothing than the limbs, a long vest, extending from the neck to the coccyx is needful. There is no objection to this being put on first. The linen chemise may be dispensed with, but in no case should it be worn next to the skin. Then come the body, or bodice, and knickerbockers. The material of which these are made is unimportant. The bodice should fit the body neatly, at the neck being an inch or more above the collar-bone, and below being three inches lower than the crest of the ilium. The lower margin overlaps the band of the knickerbockers, which at the back should cross the fourth lumbar vertebra, and pass outwards and forwards, slanting gently downwards. The weight of the knickerbockers and of the petticoat, if one be worn, is thus thrown on the pelvis. Many petticoats are certainly superfluous, and a divided skirt, which may be made of flannel or woollen cloth, will do away with the necessity for one. Finally, there is the body and overskirt, making the dress proper. Let this be as simple as possible; there will yet be room for invention and the display of good taste. In any case it must not be stuck over with bows and knots and useless buttons, or pulled up into a bunch at the back. As for the divided skirt, let no one be afraid of that because it is a pronounced imitation of the male dress, and conspicuous. It is nothing of the kind. A lady might wear it for years, and her neighbours and intimate friends be ignorant of the fact. Indeed, it is the simple truth that it is worn by numbers of ladies without the knowledge of their friends.

Ladies' evening dress is more open to censure than their morning or walking dress. The other day I was looking through the fashion prints of *La Belle Assemblée*, published in 1819 and 1820, and I saw costumes designed for the opera and the ball-room, fitting the figure, and graceful, and modest. Why cannot ladies go back to such dresses? They are infinitely more beautiful than the dresses now worn. Being shorter, and higher in the neck, and obviously not tight anywhere, they must have been comfortable and healthy. The present evening dress is almost the worst conceivable. The shoulders, upper part of the chest and back are simply nude; from this to the waist the clothing is far too scanty; while below the waist is a burdensome profusion of dress material, which is a mystery and a marvel. Here is a frigid zone, and a temperate, and a torrid zone. Will no lady come forward and teach her sisters how to equalise the bodily temperature? As I write, the news reaches me that the Queen has approved of high dresses, and a full description of the new approved dresses is about to be circulated from the Lord Chamberlain's office. If the Court would also lead in disapproving of stays, and improvers, and long trains, all the changes desired would soon be effected. It is unnecessary for me to enlarge upon the evil effects of wearing stays—the subject is threadbare. Every well-formed woman has a waist of the shape indicated in fig. 4, and the effect of tightening up this day by day in

Fig. 4.

a corset is to compress it from side to side, and make it nearly round. This interferes with the action of the lungs in much the same way as fastening the handles together would interfere with the action of the bellows. Beside the contraction of the thoracic cavity there is the displacement of the abdominal viscera, giving rise to various complications, and the wasting of the muscles covered by the stays. If a leg be bandaged in splints the calf muscles waste, and if a chest be bandaged in splints the thoracic muscles waste; and thus the stays wearer complains of a weak spine, and says she absolutely needs the support of the stays, which she will not recognise as the cause of the weakness.

The form of jackets and coats for out-door wear depends so much on the fashion of the day that remarks upon the subject must be general. The short all-round shoulder-covers cut off square some inches above the waist, are not graceful, interfere with the action of the arms and unduly

heat a small portion of the body. As bad or worse from almost every point of view is the "dolman." For general wear nothing suits better than a rather long jacket or paletôt conforming with the lines of the figure. A long loose cloak, easily put on an off will be found most useful, and an Ulster with a hood, is almost indispensable.

Millinery is also ruled so much by fashion, that it is vain to lay down precise rules. In a little book I published five years ago, I figured what I considered the most perfect form of bonnet and hat. However, ladies do not order bonnets or hats to fit them, but select from specimens in a show room. I would suggest to ladies thus making a selection to remember:—(1) That the purpose of a bonnet or hat is primarily to afford protection to the head. (2) That every covering for the head should be securely fastened on, and not carry too much sail. (3) That the trimmings, flowers, etc., should not be put on with too lavish a hand, or all form may be smothered in a confusion of meaningless decoration. As a rule bonnets are better than hats for adults, still there are exceptions. An extravagantly large hat, as the "Gainsborough," looks pretty enough as a back-ground to a sweet face in a picture, but how would such a hat look from the rear? Less inconvenient to the wearer, but as bad or worse are hats ridiculously too small, stuck on the back of the head, or on the front of an artificial top-knot.

It may be added that a good bonnet or hat should afford some shade to the eyes, and should not obstruct the hearing.

CLOTHING OF CHILDREN.

Many of the defects noticed in the boots worn by adults are almost as often seen in children's boots, yet it is of first importance that a child's foot should be kept warm and dry, and have room to move and grow. A child's feet are undeformed; let every care be taken that the first boots do not begin the distortion already referred to. The boot should be made to fit the foot on the lines laid down, the sole being *too large*, to the extent of a third of an inch in length and a sixth in breadth. A toe-piece about an inch and a quarter deep is of great service in protecting the foot, especially during rough games. To prevent the oblique displacement of the great toe, it has been suggested that a separator might be introduced between that and the next, as in the classic sandal or the Japanese shoe. However, there need be no fear about displacement of any of the toes if the boots be properly shaped and wide enough. Children need digitated socks as much as adults, except in the case of mere babies. All children, boys, girls, and infants, should wear woollen material next to the skin, up to the neck and down to the wrists. Combination garments, or little drawers and jerseys, may now be had of all sizes. Happily, nude knees and bare arms are not now in fashion—a fashion that has caused more lamentation and weeping than King Herod. What comes next is of little importance, provided that it be light, and easy, and warm. There is plenty of room for parents to display their good taste. Many of the costumes now most in favour for children are comfortable, healthy, and graceful. After the "first layer" of clothing, I recommend a long waistcoat of stockingnette web or flannel, and usually all that is needed beyond this comes under the head of costume. For a boy, let me suggest the familiar sailor dress; for a girl, what can be better than knickerbockers, a waistless jacket, and kilted skirt? Hats and caps may be of almost any form, so long as they are light and warm enough, and shade the eyes from the sun. Straw hats are convenient and pretty, but as much cannot be said of the enormous bonnets now worn by little girls. These bonnets are really the most objectionable of modern innovations in children's clothing. *Vide* fig. 5, which repre-

FIG. 5.

sents a child's head in one of the grotesquely huge bonnets. It presses somewhat on the crown, covers over the ears, limits the wearer's field of vision, catches the wind, does not fit the head, and is a prodigy of ugliness.

Is there anything special to be said about infants? As a rule the infant is too abundantly clothed. At least it would be the better for the absence of that proto-garment—its broad flannel bandage. Mothers and nurses believe in this religiously, just as writers on "art dress" believe in the Roman toga and the Greek chyton, but such faith is misplaced. If put on loosely it overheats the child, if put on tightly it compresses the thorax and abdomen. Next, there are the "long clothes," which are objectionable, if for no other reason, because they put restrictions on the free action of the legs. The long flannel petticoat is usually folded under, wrapping up the legs as in a parcel, and the long clothes over this hang down, as if to give the nurse a firmer hold of the infant. Of course anything which does not allow a baby ample space to breathe, cry, kick, and roll about, is bad. It is hardly necessary to point out also that the change, come when it may, from long clothes to short clothes, is not without grave risk, and that many an infant thus catches its first bad cold, perhaps its last too. The problem, how to cloth a baby is a very simple one. Let its things be of woollen material, woven or knitted, and let them fit. Everything should be of wool, but the bibs and diapers, and these, I may remark, should be washed, *not merely dried*, when they are wet. On the much debated question: caps or no caps for babies? I decide for the caps. Little heads like little chests, are very susceptible to cold, so it is a reasonable precaution to give an infant a light cap till nature provide one.

Special Articles.

MICROBES AND ANIMAL ALKALOIDS.[1]

By PROFESSOR PETER, PARIS.

THIS lecture may, if you please, bear the alternative title, "The Rise and Fall of the Microbian Empire." Years ago I attacked the microbe when it reigned supreme

[1] An Inaugural Lecture to the Course on Clinical Medicine.

as lord paramount over every form of infectious disease; to-day I again speak on the well-worn theme, but it is to tell how its power has waned and its influence faded away.

You will have scarcely forgotten that two years ago I showed how the implacable partisans of localisation had become the equally intransigeant supporters of generalisation. After having located a given disease in an organ, then in some part of its parenchyma and, later, in its elementary cells, they had finally displaced it altogether, and found in the alien microbe the very source of the evil. Let us take, for example, pneumonia: it used to be regarded as a fever "*febris peri-pneumonica*"—that is to say, a disease affecting the system generally, but with a special morbid localisation in the lung. Then, pathological investigation made it an inflammation of the lung itself, and the discoverers of the plastic exudation said, "Behold the disease!" but they had mistaken the result for the cause. Later, under the influence of more recent views, the investigation became microscopic, and the pneumococcus was discovered, and "Here at last," they cried, "we have the cause of pneumonia!" Very well: if the pneumococcus is the infecting agent, then a disease so engendered must be general, and we have come back pathologically to the point from which we started! But, from some cause or the other, the pneumococcus may become an endocardococcus or a meningococcus—producing endocarditis or meningitis—and so we see how the specific agent ever carries us farther from specificality—and that way madness lies! Now we are in the presence of another transformation of the same kind: solidarity passes into humoralism, and the microbe is the connecting band. The coccus is not dangerous in itself, but only through the alkaloids it generates in the humors of the body. The parents of micro-biology proclaim "animal alkaloids," and by this Abrahamic sacrifice murder their own offspring!

With untiring industry, with the most laborious minuteness, the microbe of rabies has been searched for, but in vain. But rabies is infectious, and leaving aside the microbe, they have seen, or fancy that they see, in the spinal cord of a hydrophobic animal a soluble poison, which they term "chemical vaccine." But how, by what has it been produced? Surely, without the aid of any microbe; then, indubitably by the cord itself. What! the spinal cord generate poisons? You take a fragment of such a medulla, and inoculate a rabbit with it—the latter dies. But if you previously dry it for forty-eight hours at a temperature of 35° cent., and then inoculate, the rabbit lives; and if, shortly afterwards, some of a fresh rabid cord is injected into the same animal, it still lives unaffected—it has been "vaccinated." But why? by the action of some living agent? No, certainly not, but from the effects of a chemical one. The poor microbe, it seems, is *in extremis!*

That which in earlier days won the triumph—as remarkable as it has been ephemeral—of the microbian theorists, that which made us accept the theory itself with credulous enthusiasm, was the simple fact of the indefinite growth of germs introduced into the system by some solution of continuity. It is enough, said they, to take a drop, a droplet, an atom of the poisonous fluid, and inoculate it, to initiate a growth of micro-organisms, with the result of the blocking of the vessels of the most important of our organs, and from that all the disasters we are familiar with; and it is thus, they explain, it is that so minute a quantity of a liquid (of a *liquid*, mind you) can infect the whole mass of the body. Superficial thinkers were fully satisfied; I am thankful to say, I was not. For to-day, the germ theory has been thrown overboard, and we now talk of phenomena due to the presence of poisonous alkaloids. The virus reacts, we are now taught, qualitatively not quantitatively; like that of a grain of musk, which, placed in a room, fills the whole space with its odorous emanation without losing an atom of its own weight. But this is a sad disillusion. The mystery of disease had been so charmingly solved by the intervention of the microbe; and now the animal alkaloids have come to thrust us back once more into utter darkness.

Let me again try to make it perfectly clear, as I have endeavoured to do already, that the microbes are only the *porters*, the carriers of disease and of the poison. It is not in the air that we now try to capture the pathogenic germ, but in a *drop of liquid* taken from an infected patient. It is the liquid, then, which inoculates, a poisonous fluid containing microbes—yes—*but alkaloids as well.* We take a series of broth-cultivations, and each in succession is less virulent than the last. Inoculate with the weaker, and the recipients show themselves refractory to the effects of the stronger; that is to say, we have mithridated (habituated to poison) the subjects experimented upon—just as a smoker, who is half poisoned by his first cigar, becomes quickly insensible to the action of nicotine in the succeeding ones. But—*the bacteria of the tenth cultivation are* MORPHOLOGICALLY *identical with those of the first; they have only ceased to be so* PATHOLOGICALLY. They have been deprived of *something*, and it is exactly that *something* with which they were impregnated which made them virulent; and it is thus that we can explain why the bacteria of the tenth cultivation should be harmless, or nearly so.

There are other facts no less conclusive. Koch, of Berlin, discovered the so-called bacillus of cholera; and then, having taken choleraic discharges and cultivated them, he found that the bacillus was inert if the intestines were healthy. But this same bacillus could be made—by certain artifices of cultivation, Loewentel proved—again virulent. Therefore, as this bacillus can be made to lose and then to regain poisonous activity, it is clear that the property is not innate, but borrowed. The procedure is simple: Loewental took the harmless cultivation of the "virgular" bacillus, and planted this in a paste made of flesh, pea-flour, and pancreatic juice—that is, in a kind of artificial intestinal soil, and in this way it became as choleraic as at first. So, cultivated in broth, it loses its lethal powers; cultivated *à la* Loewental, it recovers them; therefore, it cannot be in itself poisonous.

Now, let us see how the action of microbes has been explained. By some it is by gemmation, acting by their mass, mechanically. By others, it is traumatic, a destruction of the living cells, such as those of the kidney. Or, thirdly, by a more delicate physiologico-chemical action, robbing the hæmo-globulin of its oxygen, and so occasioning asphyxia. Be that as it may, according to all these hypotheses, the microbes acted *per se*. But, according to others, and now Koch amongst them, the bacillus acts by means of the animal alkaloid it separates. This is evolution, indeed; but such an evolution is suicidal. After this, cannot we explain all these pathological processes without the help of any microbes at all? Strauss has demonstrated that there are fulminant cases of cholera in which one finds few bacilli, or none. The explanation is the very simple one that the patient dies before the bacilli have had time enough to make their appearance.

Very well; when they do not exist, how can they be said to be the authors of the evil? And when there may be so few in the gravest of cases, and so many in the slightest, how can one accuse them of causing that gravity?

Once more, in phthisis, one again finds the bacillus of Koch, only it is the "rectilinear," swarming in the chronic cases but extremely few in the acute. It is clear, therefore, that it is a later visitor, and we find it existing as a witness, not as an accomplice, still less as a malefactor. And then there is miliary tubercle, in which microbes do not appear until the second or third generation. We have, therefore, virulent diseases without any microbes, some with few, and others with a great many—yet all alike fatal. The microbes were said to be the generators of disease; and we have hydrophobia, assuredly a transmissible disease, and yet without a microbe!

Peyrand, of Libourne, has tried to discover if there be in the vegetable kingdom substances analogous to the alkaloids of the animal, and he found one in the oil of tansy (*Tanacetum vulgare*). Injected into animals it produced symptoms simulating rabies; he observed, also, that chloral impeded the development of these symptoms, therefore he treated a lad who had been bitten by a mad dog with injections of chloral, and the disease did not develop. Going a step further, he inoculated animals with gradually increasing doses of oil of tansy until they became habituated to it; then he injected the virus itself: it had no effect whatever. Of the genuineness of the latter there could be no doubt, for it was taken from the spinal cord of Berger, who died in Bordeaux from hydrophobia six months after he had been "successfully" treated in Paris. So, this "simili-rabia" acted exactly like Jenner's "simili-variola," and preserved from the graver disease; and he found, too, that "intense" doses of the oil, so far from acting as a prophylactic, actually hastened the effects of the poison of hydrophobia.

I have used the term "animal alkaloid" several times, and should explain its meaning. We are indebted to Gautier for the discovery of certain bodies, true poisons, which are formed during the vital transformations of the living healthy cells. He gave them the name of "leucomaines." In the very act of living, he shows, we develop poisons which would lead to auto-pythogenia (*πύθων-γεννάω*) at all times, if we had not the power of getting rid of them by excretion. When they are not so removed we have uræmo-typhus (uræmia), cholo-typhus (fatal jaundice), athero-typhus (ulcerative endocarditis), puerpero-typhus (puerperal fever), and so on. Gautier has isolated the very agents themselves—alkaloids which the healthiest of us are ever producing and excreting, such as *xantho-creatinina* and *cruso-creatinina*. The great point of interest is that these poisons are not the result of morbid, but healthy cell-life, exactly as the cobra secretes its terrible venom from healthy gland-cells; and he has shown, also, that these poisons exert their lethal powers precisely in the way in which bacterial ferments do. Their presence has been demonstrated in the breath by Brown-Séquard and Arsonval (*vide* PROVINCIAL MEDICAL JOURNAL, March, 1888), and also in the perspiration and urine, without any trace of accompanying microbes. The saliva itself is, we know, sometimes poisonous, and it would seem that in the dog this may be induced by excessive excitement of any kind, but especially ungratified venereal. The unwholesomeness of fish during the spawning season may be due to this cause, and in India fish commonly eaten are known to be poisonous at that period. [May not this have been the source of our own venereal poison?]

It is the current coin of science to say that "the air is full of germs," and that these germs are the agents of contagion. Strauss, by exact enumeration, has shown that everyone of us walking in our hospital wards inhales 609 bacteria at each inspiration; and expires—exactly ONE! But, not to be too scrupulous, suppose we say 600 only. Now, at twenty respirations per minute, that amounts to 17,280,000 every twenty-four hours. Why, we may be said to live upon them. The lungs, according to Strauss, act as filters, and return the air bacteriologically pure, and I would add most *alkaloidically impure*, and that is of some importance, for we have seen that these respiratory alkaloids are poisonous.

And now we can estimate the almost omnipotence of vitality. I pass some hours every day in the wards of this hospital, and I breathe an atmosphere loaded with the germs of pneumonia, of phthisis, of typhoid, and yet I escape every one of these maladies. Is it because my sound organism does not "care to be ill" that it is so refractory? And thus, in the very presence of the microbiologists, we return to the old theorem of "predisposition to disease," that is to say, we only become ill when we are ill already.

Now, after speaking of unassailable lungs, let us see how open wounds behave towards these disease germs. That which Strauss has demonstrated in reference to the former, Le Fort has proved regarding the latter. "Wounds suppurate because they have absorbed the bacillus of suppuration," and, therefore, we have Lister's treatment, which aims at the placing of an impassable barrier between them. Now, without denying that this system has been of great service in surgery, let us recall the fact that it is the system of *rest*, and that it compels surgeons to carefully wash their hands and instruments. Its text is "The fear of the microbe is the beginning of cleanliness."

Le Fort will not admit the influence of aërial germs; to him the cause of mischief is contagion from the fingers of the surgeon, his sponges and instruments. To prove that the air has nothing to do with it, he leaves his patients at the Hospital Necker with their wounds freely exposed. To avoid accidental irritation only, he covers them with a wire cage under the bed clothes, and nothing else. Three amputations of the thigh, three of the leg, and a resection of the elbow have been treated thus, and they all healed without suppuration, and by the first intention. More than that, he took a platinum wire, sterilized in the flame of a spirit lamp, and transferred some of the lymph from these wounds to the usual media, and obtained beautiful cultivations of *stafilococcus albus* and *aureus*, and some even of *streptococcus*, which is the specific germ of erysipelas, and yet none of these wounds suppurated, nor showed a trace of erysipelas.

We were speaking of the resistance-energy of the organism. Metschinkoff has given us an original explanation of its mode of acting. Healthy cells, according to him, devour the dangerous germs, and so render them innoxious, exactly as a crab gets rid of offensive matter by eating it. Every organ is provided with "phagocytes" (germ eaters) of various kinds. Some are the tissue cells —these are "macrophagos." The others are the leucocytes—these are "microphagos"—which reminds us of the story of the man who had two openings, one large and

one small, cut in his stable door, one to admit the cat and the other the kitten—but between them the slaughter is incessant and terrific; so Homeric, indeed, that it needs a new Batrachomyomachia to adequately describe it.

It is some time since Robin declared that a micro-organism is only dangerous when it has emerged from an infected bed. The bacterium of carbuncle is not itself harmful, but only because it comes from a carbuncle wherein the poison lies. Bouchard and Charrin have filtered pyocyanic cultivations through porcelain (biscuit) so as to separate all organic corpuscles, and the fluid inoculated in minute doses in rabbits rendered them refractory to the original poison. Bouchard has obtained the same results with the urine of the rabid animals, the kidneys having acted as bacterial filters.

Immunity can only have practical value from its duration; that which is limited to a few days is only of laboratory interest, like the famous anti-cholera vaccination, which served for two days, but failed on the fifth. For animals, one which lasts a year or two, since they must then be slaughtered, is enough, but not for human beings. But has the mortality of rabies diminished since the use of the so-called anti-rabic inoculations? Certainly not; it has increased. Berger died six months after his inoculation, and Sinardet expired amid hydrophobic convulsions twenty-seven months after it. Do you clearly hear me? *Two years and a quarter* after his cure in the laboratory of the *rue d'Ulm*. Who can tell, then, what may be the fate of those so treated in 1886-7-8? These scientific experiments—these "vaccinations"—animal or chemical, performed so beautifully by our most eminent men, are deeply interesting; but are they of the slightest practical use to mankind? I venture to doubt it.

In the course of my medical career, which is a pretty long one, I have witnessed the glory and the decadence of many theories. I was at the death-bed of the theory of Broussais, which bound the gastric hypothesis of van Helmont to the radiants of Willis and Rega; I enjoyed in halcyon days the theory of specific numbers; then the embolia of Virchow carried us back to the regional errors of Boerhave; later on, everything was due to reflex action; and now we have hardly had time to congratulate ourselves on the birth of the microbe, when we are called upon to replace it by animal alkaloids. Once more we have drifted back from solidarity to humoralism, and experience has converted me into a philosopher.

Nevertheless, at the base of all is progress, for every theory reflects, like a prismatic mirror, a part of the truth. Broussais bequeathed us irritation; the numerical theory the germ of our instruments of precision; to Virchow we owe embolism; to Claude Bernard our more exact neurology; and to the microbians, the virtue of cleanliness. Thanks to them; how many people have learned how much better it is to be clean than dirty, to appreciate the excellence of pure water, and the advantages of wholesome food.

The error has been too great a fondness for generalisation, for, believing that every theory reflected the whole of the truth, it is for us, for you, to attempt to combine these fragmentary images, to bring into one focus the scattered rays of the clinical spectrum, and with such perfect fitness, in such balanced order, that of the result we may say "*Magna est veritas et prevalebit?*"

G. F. Cadogan-Masterman, M.D.

HEALTH RESORTS OF THE WORLD.

XXVIII.—SOMERSET.

WITH SPECIAL REFERENCE TO WELLS.

By Alfred J. H. Crespi, of Wimborne.

Somerset, the land of the ancient Sumorsætas, has always been remarkable for its verdure and fertility. Like Dorset, the land of the Dorsætas, Somerset was not a district governed by a chief central city in the fashion of Worcester, Hereford, Warwick, Gloucester and Stafford, but was peopled by a tribe having no important towns. From the departure of the Romans to our times matters have remained little changed, the towns are many, but small and little known: there is no large central place, which from its superior importance overshadows all its neighbours. Bath, certainly, is a city of great antiquity and considerable population, but it is at the very extremity of the county; while Wells and Glastonbury, which are more central, never were accessible, and at one time must, for months every year, have been cut off from the rest of the world by floods and marshes. Of late years the coast has become better known from the growth of several pleasant enough towns, Clevedon, Weston, and Portishead. But in this article I do not propose describing these three little towns; I shall rather deal with a district that in many respects has no equal in the kingdom, and which though the centre of much ecclesiastical life and activity, is not visited as it deserves. I have known Wells for thirteen years, and I have made two long visits to it, not idle visits, for I think I may claim never to be idle, but busy, with much to do and see, and at other times I have stayed at Weston, Clevedon, and Portishead, so that I can claim to speak with some authority of all parts of the country.

With a few exceptions, such as Lincoln and Durham, our English Cathedrals and Abbeys generally stand in rich and fertile valleys, near sparkling streams, where art uniting with nature the most lovely effect is obtained. This is true of Wells and Glastonbury, of Llanthony, Tintern, Gloucester, Tewkesbury, Worcester, Bath, and Valle Crucis. Generally speaking these time honoured edifices are surrounded by a beautiful setting of hills to which they form the central brilliant. Every visitor to the magnificent memorials of the zeal and self-sacrifice of the monks, who flourished during the great ages of the Catholic Church, must I think come away feeling more kindly and tolerantly towards the patient and studious recluses, who in times of violence and cruelty, kept alight the lamp of religion, succoured the weak, and offered a peaceful asylum to the disappointed and oppressed. An almost painful effort is required to picture the age of St. Anselm, whose life has been so gracefully written by Dean Church, and who was adjudged by Dante, never lavish but always just in apportioning praise, worthy to rank with the noblest of his contemporaries. When St. Anselm wandered from Aosta, in Northern Italy, and took refuge in the Norman Abbey of Bec, then at the height of its power and glory, the cloister alone promised a quiet home to the timid and retiring student. In those days might was right, and woe to him who could not enforce his claims. War ran riot, and human progress was necessarily slow and uncertain, indeed the wonder is that anything durable or great was accomplished amid such conditions. The Church of Rome was the only barrier against universal licence and spoliation, and but for her England might have sunk into a barbarism little less pro-

found than that of the North American Indians of the time of the Pilgrim Fathers. It is the custom of a certain school to talk contemptuously of the monks, to deny them the sense of beauty, and even to speak of them as chancing to alight upon beautiful sites, and rearing great ecclesiastical buildings the loveliness of which they could not appreciate, to compare them in short to the honey bee, which, guided by an unreasoning instinct, weaves its delicate tissue of fairy cells. Can anyone who knows and loves our mediæval churches as they deserve, accept such a fable? It is no more possible that a Congo Negro, or an Eskimo fisherman could produce a second Divine Comedy, or a fitting companion to Paradise Lost, than that rude, coarse and sensual men should have designed and executed such miracles of art as Tintern, Lincoln, Ely, and York. In those almost unknown and more than half forgotten masters of architecture the sense of beauty must have been developed in a preëminent degree; they were equally remarkable for untiring patience and industry, to which we, with the command of almost perfect mechanical appliances, can hardly do justice. Had they enjoyed our advantages, they would have left monuments still more stupendous, compared with which, our finest modern buildings would be mean and contemptible. Our appliances and resources enable us to accomplish in a week what cost them a year, and we are able to take their designs as our models, but in spite of this, the new Cathedral of Truro will certainly not rival the vast pile of Durham, and Liverpool, should the scheme for building a Cathedral there be revived, will not with all its wealth and enterprise give us another Westminster or Amiens.

It is curious in narrowly inspecting the pillars and windows of such a church as Peterborough to notice that the work is less true than our masons would put together—in other words, so rude were the appliances at command that the departure from straight lines is marked and frequent, and one side of a window or pillar rarely matches or corresponds to the other, nevertheless in spite of the greater mechanical precision of modern work, how vastly superior in design and general beauty of effect is the ruder and rougher execution of our ancestors.

In spite of obvious differences, the camp and the cloister had something in common—the severe discipline of the monastery, the unhesitating submission to authority, the long night watches, and the untiring struggle against sin, were manly and heroic. For centuries, therefore, stern and ruthless soldiers found that retirement to the cloister reminded them in some degree of their former life; and when, weary of war, or broken by wounds and years, they awoke to a dim consciousness of their sins, and the need of preparation for the awful change awaiting them, they often doffed the morion and the cuirass, and donned the monk's sad coloured garments. Two graceful and brilliant articles appeared in the *Nineteenth Century Review* of 1884 on this very subject, the first from the pen of Dr. Augustus Jessopp, on "Daily Life in a Mediæval Monastery;" the other from that of the Rev. Father Cody, O.S.B., on "Daily Life in a Modern Monastery;" both bear out my view of monastic life in its most favourable aspects. It is true there may be another side to the picture, on which I need not here dwell, and pride, arrogance, and turbulence might not have been unknown in the cloister. In the devotion and self-sacrificing energy of those poor monks, there was, nevertheless, much to admire: and what other proof is needed of this than the vast ecclesiastical piles which they raised to the glory of God. It requires a strong imagination to grasp that those stupendous cathedrals and abbeys, those beautiful country churches which adorn hundreds of our ancient villages were designed and built by men, who were without roads and canals, railways and steam, and who had to do everything and carry everything with appliances and amid conditions hardly less rude than those of a newly cleared American settlement, far from stations and high roads. Americans may well look with wonder on the most glorious temples ever raised in honour of the Most High! Should a hundred cities of palaces fringe the banks of the Ohio, the Hudson, and the James; should Florida and Louisiana teem with thriving millions, and be freed by science from the plague of malaria and yellow fever, one thing will always be wanting to them—no Norman Abbeys, no Gothic Cathedrals, no Mediæval Castles will tower above the encircling houses. American enterprise and English wealth would have no difficulty in faithfully reproducing Salisbury Cathedral, Romsey Abbey, and St. Mary Redcliffe, but never will a real addition be made to the great churches of the first order. This is a melancholy reflection. When I think of the delightful climate of America, of the transparent atmosphere, and life-giving sunshine of New York, Philadelphia, and Richmond, and compare the broad avenues and vast open spaces of those cities with our narrow, dingy, old world streets and fog infested squares, the thought forces itself upon me that, though those greater and more prosperous cities can never boast of the historical associations of Europe, it would be something could exact reproductions of buildings, among the chief glories of the less favoured Old World, be reared in their midst. It would be an invaluable education were American energy and wealth to endow three or four of the bright sunny cities of the Atlantic seaboard with faithful copies of Amiens, Wells, or Lincoln. There would be nothing difficult in this, and money could hardly be more wisely laid out. Most Americans could get to Richmond, Philadelphia, or Washington, but comparatively few have leisure, means, and opportunity to cross the Atlantic and see the gems of the Middle Age in their damp and cloudy settings. To a cultured American it must be a singular awakening to visit an English or French cathedral, to enter its doors, and sit bathed in the sunlight streaming through its windows. He may at home have seen opulence, and energy, and the promise of achievements greater than Europe can show, but America has nothing like the Angel Choir of Lincoln, the Palace of Versailles, the ruins of Tintern, and the towering elevation of Amiens; nothing even remotely resembling the Tower of London, the wooded amphitheatre of Kenilworth, and the majestic masses of Chepstow and Ragland.

Wells and Glastonbury stand in a rich, alluvial country, enclosed by beautiful hills of moderate elevation, but of indescribable loveliness. Far as the eye can reach extend fertile fields of so green a hue, that they rival the far-famed meadows of the Valley of the Wye and of Devonshire. Wells takes its name from three springs in the palace garden, and was once known as Welne, Wielia, Fonticula, and Ad Aquas. There is reason for agreeing with Professor Edward Freeman, that Glastonbury is perhaps the most interesting town in England. Its time-honoured memories rival, if they do not eclipse, those of every other British city. At Glastonbury the past and the present meet: the British Ynisvitrin, or Glassy Island; the Insula Avalonia of the Romans; the Glaestingaburh of the Anglo-Saxons; the Aestiva Regio of

the mediæval writer; the Mystic Isle of Avalon, and the Fair Isle of Avalon of the poet; the spot where shadowy tradition relates that the banner of the Cross was first unfurled in 61 or 63; the resting-place, according to legend, of St. Joseph of Arimathea and his son Josephus; the sepulchre of St. Patrick, the apostle of Ireland; of Gildas, the historian; of St. Dunstan, that commanding personage and pronounced individuality of the Dark Age; of the Venerable Bede; of King Coel, the grandfather of Constantine the Great; of King Arthur, and the frail, but much-suffering Guinevere; of King Eadmund the Magnificent; Eadgar the Pacific; Eadmund Ironside; and a hundred others. Well, we are not called upon to inquire too curiously into these ancient traditions, and some of the foregoing probably rest elsewhere, although many undoubtedly repose beneath the shade of what remains of the still splendid Church of Glastonbury, for there is nothing improbable in some of the legends. When a spot had acquired a national reputation for sanctity it was possible, in spite of bad roads and long distances, that the bodies of departed heroes and kings might be conveyed by loving and tender hands to the most famous shrine within reach. England is a very small country, and a week would suffice, even in the Middle Age, to convey a body from Plymouth, or Warwick, or London, to Avalon. Those were ages of faith and reverence, and the modern Nonconformist spirit, which seems almost incapable of appreciating, indeed, of perceiving beauty, was then unknown. I once met an old friend and his wife, wandering aimlessly about the streets of a large town. They were bright and shining lights among the Baptists, and had considerable wealth, and some intelligence of a practical kind. As they had nothing to do, I persuaded them to accompany me over the grand and memorable Cathedral in the next street. It chanced to be one of those days of an English summer, when the sun was shining in a sky less hazy than its wont, and the atmospheric conditions were singularly favourable. But I might have spared myself all trouble. The old deacon knew nothing of the worthies buried within the walls of the Church; and as for aisles, transepts and choir, my powers of description did not make the smallest impression on him, and he and his wife, after yawning a few times, and looking painfully uninterested, ran off, leaving me astonished at their obtuseness. Again, a few years ago I was at Glastonbury, with some hundreds of worthy people, Dorset and Somerset Dissenters chiefly, who had met for a temperance conference. The Abbatial buildings had been temptingly thrown open to visitors, but in vain; the church, Abbot's Kitchen, and the Abbot's Barn, had no attraction for them, and only half a dozen wandered listlessly about the ruins, every stone of which would have repaid reverent study. To appreciate the glories of the past needs a certain constitution of mind, and some tincture of culture and scholarship. An English labourer has not imagination enough to see beauty in a Cathedral or painting; and homely Nonconformists, however conscientious and excellent, are incapable of appreciating treasures which in the eyes of the scholar and the antiquary invest life with half its joys.

Wells is in the Eastern Division of Somerset, at the foot of Mendip, a low range of pretty and fertile hills; it is twenty miles south of Bath, and twenty-one south-east of Bristol. It has been a place of some importance since the days of Ine, Kinglet of the West Saxons, who conquered it in 704. It received its first charter from King John, in the third year of his inglorious reign, and returned members to Parliament from 1297 to 1868. The population of the parish is about 7,690, though the city has 3,000 less. In the business part of the town there is little to interest the stranger, the ecclesiastical buildings excepted. The streets are clean, fairly broad, and well laid out. There are few signs of modern improvements, and scarcely any new houses or shops, except half a dozen small villas near the stations; of the last, such as they are, there are three, though Wells, in spite of this, is practically cut off from the world, and is without express and main line trains—standing, as it does, in a complicated network of cross-country slow lines. There is an air of prosperity in the better-class streets, and not more poverty than usual in an old country town. Near the Cathedral some massive and imposing mediæval houses are noticed, some among them of singular beauty and great size. Most belong to the Chapter, and are inhabited by members of the Cathedral body.

Wells has an atmosphere of its own that at once strikes the visitor. In his well-known and scholarly work, on the Cathedral Church of Wells, Professor Edward Freeman does ample justice to the unique character of the place, besides tracing the steps by which modern cathedral establishments assumed their present peculiar constitution. Mr. Freeman's studies and his long residence at Wells make him, perhaps, our greatest living authority. The Cathedral dominates the town and dwarfs the handsome houses near; but though it possesses that feature in common with many cities of more pretension, Wells Cathedral is *the* city. It is at once evident that the lay population has been superadded to the clerical, and that originally the church with its cloisters, palace, deanery—the last probably the noblest in England—and close must have been practically the entire city. Taking it as a whole, there does not exist anywhere else in England so peculiarly ecclesiastical a city. Walls it never had, nor did it need protection, and, unlike nearly every other cathedral town, it never had a castle, and never acknowledged a feudal lord the rival of its spiritual chief. A thousand years have passed since a community of secular canons, under the patronage of St. Andrew, first established themselves on the spot. The see of Wells is said to have been founded in 909 by King Alfred's son and successor, Edward the Elder, and its first bishop was Æthelhelm, previously Bishop of Glastonbury, and subsequently Archbishop of Canterbury.

From whatever point the cathedral, and for that matter the city, is approached, the principal object is the vast church towering above everything else; not so much from superiority of site, for the north side of the Cathedral is several feet below the street-level, but from sheer massive bulk and lofty elevation. The best way of approaching it is across the Green, a large and admirably-kept lawn traversed by broad gravel walks and shaded by fine old trees, the latter effectually darkening the rooms of the houses close to which they rear their lofty heads. Then the visitor stands before the magnificent west front, reputed the finest in England, though Peterborough is very grand, and one of the most imposing in Europe, and Ely too is magnificent. The west front of Wells consists of three portions—a north and a south-west flanking tower, and a main central division. The west front is so good, and the design so admirable, that it needs an effort to believe that it was built in portions and at different times. The south-west tower dates from 1366, and the north-west from 1407-1424. Both are in the Perpendicular style; but the remainder of the west front is Early English, and is con-

sidered to be the work of Bishop Jocelyn Trotman. It was completed in 1242, two years after the birth of Cimabue, the Florentine, of glorious memory. To describe the West Front is impossible. Not the most flowing pen would convey to anyone who had not seen it, still less to one whose eyes had never rested on a cathedral of the first order—though Wells is only in the third class—what architecture can accomplish with material apparently so little plastic as stone. In the niches are placed 300 colossal statues, which the restorations gave favourable opportunities for closely examining. They are arranged in nine tiers, and were originally carefully grouped, making it probable that they represent or allegorise many incidents of scripture and of natural history. They have also been thought to illustrate the *Te Deum*. The conjectures and guesses of writers have been wild in the extreme, and can only be excused by the wide latitude which the figures themselves allow. Quaint old Thomas Fuller, speaking of this marvellous assemblage of monarchs, angels, priests, and nobles, styles it 'A masterpiece of art, England affording not the like,' and modern authorities claim still higher honour for it. The breadth of the front is 150 feet, slightly exceeding the width of Notre Dame, at Paris, and of Amiens Cathedral-contemporary buildings, though the elevation of the interior of the latter makes it incomparably more imposing. Wells, like most English cathedrals, is comparatively low and narrow. Here I had better give the dimensions of the church. Its extreme length is 415 feet, and the extreme length of the transepts 150; the nave is 192, and the choir 117 feet long, while from the ground to the finials of the centre tower the distance is 182, and to the summit of the western tower 130 feet; the interior height of the nave is 67 feet, and of the choir 73 feet, while the diameter of the chapter house is 50 feet, and the height 41 feet. The magnificent cloisters are about 160 feet from east to west, and 200 from north to south. The cathedral is built in that cruciform fashion almost invariable in English churches of great size, and of course closely resembles a cross. French cathedrals, nearly always like ours, cruciform, have commonly vast chapels surrounding the nave and choir. Their area is larger, and their elevation usually far greater than that of English cathedrals, which are long, narrow, and low, and from terminating in a lady chapel—generally very low and narrow—are much less remarkable for vastness than a mere comparison of their length and breadth with those of French cathedrals would seem to indicate.

It might not be amiss here to digress and to lay before the reader some particulars respecting the size of famous English Churches, which, with some difficulty, I have managed to collect. York Minster is 518 feet long, and the length of its transepts is 241 feet; the west towers are 196 feet high, and the central tower or louvre, for it is open in the interior, rises 188 feet above the pavement; the nave is 250 feet long by 103 feet broad, and 92 feet high; the chapter house has a diameter of 57 feet, the choir is in nine divisions, and from the gates to the eastern end is 222 feet long and 46½ feet wide; the eastern window on which are represented 115 historical subjects, is 75 feet high by 32 feet wide. St. Paul's has a length of 500 feet; the western front, with the flanking towers, is 180 feet broad; the transepts, including the doorways of the porticoes, are 250 feet across; the entire circumference of the church is 2,292 feet, and the diameter of the dome 145 feet. Salisbury Cloisters are square, and extend 181 feet 9 inches, and the breadth of the ambulatory is 18 feet. Canterbury central tower rises 234 feet, and is 35 feet wide; the total external length of the cathedral is 545 feet by a total external breadth of 156 feet, and the crypt, a remarkable part of the building, is 230 feet long, with an extreme breadth of 130 feet; the cloisters are a square 134 feet in the side, and the chapter house is 92 feet by 37 feet. Lincoln cloisters are 118 feet by 90; the chapter house, in shape a regular decagon, is 60 feet across and rises 42. The Central or Broad Tower is the loftiest mediæval square tower existing in England, and is beyond all admiration. To the top of the embrasure it rises 238 feet, the height to the gutter is 244 feet, and to the top of the vanes 271 feet 2 inches. It once served as the base for a tall spire of timber covered with lead, more than 250 feet higher, making a total elevation of 525 feet, or 121 feet higher than Salisbury Spire, and nearly twice as lofty as Grantham. This marvel of mediæval energy was destroyed by a tempest, January 31st, 1548. The breadth of Lincoln nave is 80 feet, and the length of the west transept 222. Chichester Bell Tower, the only one in England, rises 120 feet, and is extremely plain, though very massive; the nave is 156 feet long by only 26 feet wide, but the original aisles were 12 feet apiece, and the additional ones add another 14 feet, giving a total internal breadth of 91 feet 2 inches; the transepts are 130 feet long by 34, and the Choir is 105 feet by 36, having an extreme breadth of 60; from Choir to Lady Chapel the distance is 26 feet 2 inches, and the Lady Chapel is 62 feet 9 inches by 20 feet 7 inches; the Spire rises 271 feet; the vaulting of the nave 61½ feet, and the Choir 59 feet 2 inches; under the Tower the ceiling rises 67 feet, and the height of the Lady Chapel is 22 feet. The Nave of Rochester is 150 feet long from the western porch to the steps of the Choir; the breadth between the pillars 33 feet, and between the walls 75 feet; the choir is 156 feet long; the west transept is 122, and the east transept 90 feet long; the extreme length is 306 feet; the height of tower is 156 feet, and the breadth of west front 94. The length of Winchester is 545 feet; length of transepts, 208 feet; from choir screen to altar, 135 feet; length of Lady Chapel, 54 feet; length of nave, 250 feet; length of Presbytery, 70 feet; the breadth of nave is 86 feet, height 78; and breadth of west front is 118. Hereford nave is 144 feet long; Gloucester, 174; Durham, 260; and Ely, perhaps the largest in Great Britain, is given as 327 feet. Christchurch Cathedral, Oxford, is 152 feet long; transept, 101 feet; height of nave, 41; and of choir, 37. The internal length of Exeter is 380 feet, and the breadth, 72 feet; length of nave to choir, 168 feet; then to new Altar Screen, 127 feet; the transept is 138 feet long; height of vaulting, 66 feet; dimensions of Chapter House, 50 feet by 32. Norwich, from West door to Choir screen, 212 feet; length of transept, 177 feet; breadth of nave, 72 feet 7 inches; from Choir door to point of Apse, 170 feet; breadth of Choir, 45 feet; height of vaulting, 73; Spire and Tower rise 313 feet; Cloisters, a square of 150 feet in the side. Peterborough, West front, is 156 feet wide; length of Nave from West wall to Choir, 266 feet 3 inches; total width of Nave, 79 feet 4 inches; length of transept, 184 feet 9 inches; length of Choir, from entrance to Apse, 128 feet; thence to East wall, 35 feet; breadth of Lady Chapel, 83 feet 5 inches; total external length of church, 479 feet; general height from pavement to ceiling, 81 feet: height of Lantern, 135 feet. Ely, interior dimensions, 517 feet; breadth of Nave and Aisles, 78 feet; length of transept, 179 feet 6 inches; vaulting of Choir, 70 feet high;

dimensions of Lady Chapel, 100 feet by 46 feet, and height 60.

To return to Wells: on passing through one of the small, mean doors in the West Front, the general effect is imposing; fortunately it is not disfigured by rows of pews, so that its severe simplicity is in no degree marred. Few cathedrals have been so admirably restored and with such scrupulous fidelity to the original design and appearance. Wells Cathedral is little changed: it boasts of no gorgeous illuminated work, no rich decoration like the ceiling of Worcester, but opens on the view in its pristine plainness. Just under the central tower there are some singular sub or inverted arches, the simplicity and massiveness of which are among the most striking features of the Church. They date from 1338, and were built to resist the enormous weight of the central tower, which was tearing the body of the edifice asunder, and they have admirably served their purpose through all these centuries. The transepts, though small, are in harmony with the rest of the structure, and from them the beautiful choir is best entered. At Wells there is not unfortunately, as at Lichfield and Worcester, an uninterrupted view from end to end, and the screen, as that distinguished writer, Edward Freeman, has suggested, ought to be removed, to open up a full view of the interior. Many cathedrals are disfigured by screens and partitions, intercepting a full *coup d'œil.* The first three bays of the choir eastward are, like the nave, Transitional, while the second three, between the throne and the retro choir, lighter and more graceful, are Curvilinear. The Bishop's throne, a piece of Fifteenth Century work, is striking. Before leaving the Cathedral, it is well to observe that the view eastward, as one stands in the choir, near the Organ Screen, is beautiful, especially on a bright sunny morning. Many cathedrals, from their vast size and the comparative smallness of their windows, require brilliant sunlight to be seen to perfect advantage, and I need hardly remind the reader—that even the South of England does not enjoy the climate of Colorado, so that, generally speaking, casual tourists do not often see our great churches to the best advantage, but come away impressed more by their coldness and gloom, than their brightness and warm glow; but when seen to perfection the effect is never forgotton. Looking East the choir is seen to retain the severe simplicity of the Middle Age, and the attention is arrested by the slender, tapering columns and delicately painted windows of the Lady Chapel, distinctly seen over the low altar screen. Perhaps on leaving the choir, and closely examining the remaining portions of the edifice a little disappointment is experienced, as everything is so plain and lacks colour, but the antiquary does not desire alteration or embellishment, least of all the officious interference of house decorators, who have been permitted to try their 'prentice hands on the interior of some of our noblest churches. The view from the summit of the Central Tower is extensive, indeed magnificent, and in the clear atmosphere of America or Switzerland would make a deep impression. As it is, the visitor must expect some slight haze if not actual fog. In August, 1879, when I was living at Wells, the wide valley for weeks resembled, in places, an inland sea, from the terrible floods of that dismal summer. On a favourable day the central plain of verdant and fertile Somerset is seen at one's feet, and in summer the deep green woods and meadows almost reconcile one to the damp, without which they could not retain their verdure through the summer, or what we in England call summer, that is the season of occasional bright sunny days, with long intervening spells of cloud and rain.

Another strange heirloom must be examined—the famous clock placed in the western side of the northern transept. This curious clock was the work of Peter Lightfoot, a monk of Glastonbury, in 1322, and did good service in that Abbey before its removal to Wells three centuries ago. It keeps admirable time, though the restorations of modern watchmakers have had more to do with preserving it in good repair than antiquarians like to admit: the ancient clock in the West Tower of Wimborne Minster has many resemblances to that of Wells, and is from the same master hand.

Perhaps the superb view of the old capitular buildings from the Shepton Mallet Road, and from the meadows near the Bath Road is not to be surpassed by anything in the South of England. Looked at from that point, the Cathedral seems to stand on slightly raised ground, and its noble proportions are more clearly perceived. It is of little use visiting such places as Wells and Oxford once or twice. With all works of high art, time is needed to develop the full effect, if I may so speak, and not till the eye has again and again feasted upon them, are all their beauties perceived. Wells Cathedral from the spot just mentioned, must be seen a dozen times to make the lasting impression on the mind which it ultimately leaves. Besides the Cathedral, Wells has two fine churches—St. Cuthbert's and St. Thomas's. The former, said to date from the latter part of the Twelfth Century, is of great size, with transepts, choir and nave, and a noble tower, one of the finest in Somerset, and only eclipsed by Wrington. Somerset is famous for its beautiful and lofty church towers, built under the influence of Glastonbury. St. Thomas's, the other church, is modern, and was only completed thirty years ago, but though small, it is elegant and pretty, and is noteworthy for its tapering and graceful spire, and fine chancel; the latter, terminating in perfect apse, has extremely beautiful stained glass windows. This church was built and endowed by Mrs. Jenkins, widow of the munificent and learned Dean, to whose correct taste the restoration of the Cathedral is largely due. Dean Jenkins did not live to see the completion of his task: he died March 7th, 1854, and on the fourteenth, the choir of the Cathedral was re-opened, and his funeral obsequies, by one of those coincidences stranger than fiction, were at the same time celebrated.

Another striking object is the palace—most perfect of episcopal residences, and only rivalled by the ruined pile of St. David's—a noble battlemented mansion of irregular architecture, commenced over 800 years ago. A deep moat, and lofty, well preserved walls still surround it; it contains a magnificent dining-hall, and a long and stately drawing-room, The last place I can mention is the Vicar's Close, two parallel rows of ancient and picturesque houses, designed and built four centuries ago by Bishop Beckington's executors; they have been a good deal mutilated as to effect, though improved as places of residences, by recent alterations. I think that it must be confessed that I have made out a good case for regarding Wells in a different light, and including it among the health resorts of our land. Lodgings are neither dear nor scarce, and the Vicar's Close can usually accommodate several sets of visitors; while in many other parts of the little city rooms could be found, and the hotels too are very respectable. There are many other objects of interest to the antiquary and the botanist. Maesbury

Camp, for instance, is only a short walk, and is very perfect, and in August it is a good hunting ground for mushrooms. Wookey Hole is remarkable for its pre-historic remains; the Ebbor Rocks and Cheddar are great natural marvels, and in the clefts of the rocks ferns of many species are plentiful, and flowers flourish exceedingly. But, after all, the interest in the neighbourhood centres on its being the place where Christianity was first planted in England, the first church having been built in 61 A.D., and from that time to this Wells and Glastonbury have been famous for their noble churches and tender memories, and the earnest wish of every good man must be that their glory will never depart, but that they will long remain intact, connecting us with the distant past, and with a life that has for ever passed away.

THERAPEUTICAL NOTES.

FROM OUR BERLIN CORRESPONDENT.

The scope and aim of the notes—Sulphonal—Strychnine in delirium tremens—A new treatment of erysipelas—Glycerine suppositories—Lanolin combinations in skin disease—α-Naphthoic-acid collodium and wool—Permanganate of potassium in the diseases of women.

WITH my contribution of to-day I shall begin, under the foregoing heading, to supply the readers of this journal with particulars of anything new or striking which appears on the therapeutical horizon. It is clearly impossible for busy medical men to refer to all the original papers which appear in scientific publications, specially if they are in foreign and more or less unfamiliar languages, in order to take note of every improvement effected in medical treatment or in pharmacology. Such innovations in therapeutics are very commonly originated in Germany, where the conditions are most favourable to the carrying on of the necessary researches—in the numerous clinics—and of making known the results—in the equally numerous medical journals. I need only remind English readers of the introduction of such remedies as the new antipyretics—antipyrine, phenacetin, etc.—of salol, and of the new hypnotic sulphonal, as instances of recent additions to *materia medica* which have already acquired some reputation, and which made their *debût* in the field of medicine in this country. It will therefore be my duty to report to you on such new remedies and their application as are recommended by continental physicians, and also to call attention to later and further developments in the therapy or application of such remedial agents as have already taken a permanent place in our *armamentum medicamentorum*.

When sulphonal first came out it was offered principally at a price which was too high to enable it to be widely or largely used as a hypnotic. Consequent, however, upon the competition of the manufacturers, the product became considerably cheaper, and now one of the makers is said to have discovered a new method of preparing sulphonal which is much less complicated than that hitherto adopted, and which may therefore enable the compound to be sold at still lower rates. As in this country at least the remedy is increasing in favour, such a result as that intimated is much to be desired. Drs. Kronfeld and Löwenthal, of Vienna, publish the results obtained by them from the administration of usual doses (15 to 30 grains) 220 times to 40 different persons. The hypnotic was given every evening at seven, and produced sleep in from a half to two hours afterwards; very seldom a longer time elapsed before the manifestation of its effects. The result was happy in all the cases, and in 79 per cent. of the whole they succeeded in producing the desired hypnotic condition.

Some attention has been given in Germany to the recommendation of the value of strychnine in delirium tremens, which, it seems, would be worthy of further trial. In a particular case described by Dr. Ramos neither two-thirds of a grain of morphine given in a single night, nor half an ounce of tinct. opii, produced the slightest effect, which may also be said of the use of hypnone, urethane, and paraldehyde; sleep however, and ultimately a cure, was effected by the injection of one-twelfth grain of strychnine in a one-per-cent. solution at 9 a.m. During the few following days altogether two-thirds of a grain of strychnine were given, and the patient completely recovered. Although before the injection two-thirds of a grain of morphine had no soporific effect at all, afterwards one-sixth of a grain produced a sound sleep.

It is not always necessary to cast about for a new and fashionable remedy in order to treat disease. A comparatively simple and very ordinary agent will sometimes produce the happiest results. This is the moral of a communication from Behrend (*Berliner Klinische Wochenschr.*) on the treatment of erysipelas by spirit. The author had had under his care a good many patients suffering particularly from facial erysipelas, some of which were very bad cases. Ninety per cent. alcohol was applied regularly as a lotion three times daily, surfaces of about an inch in diameter being also rubbed with the liquid. Although most of the patients pursued their ordinary avocations while under treatment, the disease was arrested in every case, and the success was sufficiently marked as to justify further trial.

Of galenical preparations few have been more generally used and appreciated here than glycerine suppositories, which are favoured alike by medical men and by their patients. The difficulty of getting certain patients to take purgatives is well known and recognised; they refuse pills because they cannot swallow them, and decline draughts and liquids generally as nasty-tasting. Warm water or soap-water injections *per ano* are sometimes advisable, but the public generally lack the requisite knowledge or handiness to administer them; a second person is frequently required to carry out the physician's directions, and this introduces an objectionable feature for sensitive persons. Glycerine injections however are known to be very efficient, even in so small a dose as thirty to forty minims, and the idea of administering this quantity in a suppository has naturally met with favour. Their use is free from the objections referred to in the foregoing lines, and they have often aided the medical man over a trifling, but none the less real difficulty.

Dr. Stern, a specialist in skin diseases, publishes in the *Therap. Monatsh.* some notes on new combinations of lanolin. "Sapolanolin" is a mixture of 2½ parts of anhydrous lanolin to 2 parts of pure soft soap. With this base all medicaments may be mixed with the exception of salicylic acid. The author used it for applying boric acid, tar, white precipitate, resorcin, etc. These ointments were found to be specially advantageous in inveterate infiltrated

eczema, in mycosis and seborrhœa. Against psoriasis capitis he used an ointment made as described hereafter :—

℞ Hydrarg. precip. alb. ..... ʒ j.
Saponis mollis ..... ʒ iv.
Lanolini anhyd. ..... ℥ jss.
M.

Anhydrous lanolin is of course simply the ordinary lanolin of commerce, deprived of its 25 per cent. of water. Sapolanolin with white precipitate is, according to the author, just as effective on the head as chrysarobin is on the body. As a paste which adheres to the skin, without necessitating the use of a bandage, he used a mixture of—

Oleum olivæ..... ʒ ij.
Cera flava
Lanolinum anhyd. ana ..... ℥ ss.

The ointment is a pale yellow colour, and of thick consistence. It can be mixed with all other ointments when, for the treatment of eczema, the use of such a paste is indicated. Another suggestion of the author is the use of lanolin injections for the urethra, such as the following :

℞ Zinci Sulphatis ..... gr. x.
Aquæ ..... ʒ ij.
Dissolve and add to—
Lanolini anhyd. ..... ʒ v.
Olei amygdal. ..... ℥ iij.
M.

Or as under :—

℞ Acidi salicylatis..... gr. v.
Dissolved in—
Olei amygdal..... ℥ iij.
Lanolini anhyd. ..... ℥ j.
M.

Injections are made with an ordinary syringe, and it is found that the medicaments are very readily absorbed by the mucous membrane.

It is now six months since alpha-oxynaphthoic acid was brought out as an antiseptic. Helbig *(Therap. Monatsh.)* records what has been effected by it so far. He recommends a collodium made from it (0.5 per cent.) as a substitute for iodoform collodium, as it is a very strong antiseptic. It has the advantage over the iodoform preparation of not irritating the skin of sensitive subjects, and of being more stable. There can be no doubt that iodoform collodion is by no means a satisfactory preparation. Efforts are being continually made to improve it, so that this substitute should find a wide field for trial. The same author recommends an antiseptic wool in the treatment of ulcers and wounds. He prepares it as described under :—

℞ Acidi α-oxynaphth. ... ʒ i.
Spiritus vini rect..... ℥ viij.
Glycerini ..... ℥ iss.
Fuchsini ..... gr. $\frac{1}{12}$
M.

The resultant liquid is sufficient for seven ounces of wool, and gives a product which, when dry, contains about 1.4 per cent. of acid. The paper shows, on the whole, that there is plenty of room for good new antiseptics, although we have so many already.

Dr. Lwow has been trying permanganate of potassium in 187 cases of various uterine and vaginal affections. He obtained beneficial results by the daily administration of from four to six grains, in thirty-two cases of generally healthy but somewhat chlorotic girls, who suffered from decrease in the quantity, or from painfulness of menstruation. Women with an unnaturally strong involution of the uterus after delivery, or with atrophy of that organ or of the uterus, were benefited by the remedy, even when two years had elapsed since the last pregnancy. The same dose of permanganate given for three to six months was very successful in restoring menstrual regularity, even when the disturbance was of considerable standing. In sixty-two cases of involution of the puerperal uterus the remedy was also used with benefit, although in some instances it failed. In sixty-five cases of blenorrhœa of the vagina and uterus, permanganate of potassium was no use; the same was also true of eleven cases of premature arrival of the climateric, in which the menstruation ceased between thirty-five and forty years.

Reviews.

Lectures on Ectopic Pregnancy and Pelvic Hæmatocele. By Lawson Tait, F.R.C.S. Edin. and Eng., LL.D. Birmingham : *Journal* Works. 1888.

This book is not avowedly controversial; yet it must be regarded as the outcome of controversies which have marked the past few years. Though wearing the calm exterior of clinical lectures its pages recall debates to the memory which are nowhere mentioned in the work—*e.g.*, that which a recent writer calls "the splendid pioneer work of Dr. Francis Imlach, of Liverpool, in establishing the relation of extra-peritoneal hæmatocele to ruptured tubal pregnancy," and the little episode connected with it, are constantly present to the reader's memory. Another sentence from the same recent writer reads thus : "Tait says when you don't know what is the matter with a woman, cut her open and see. Now, Mr. Tait never said anything of the sort." One hardly knows what to think of such a charge, till one finds the explanation in the present volume; for therein are a few expressions which, taken apart from their context, seem to make Mr. Tait speak of "flinging diagnosis to the winds" as a thing which "only fools wait for." This enabled opponents to accuse Mr. Tait of disregarding diagnosis and preferring to operate without it. In these lectures Mr. Tait's real position is made perfectly clear; it is that when a woman is faint, blanched, bloodless, pulseless, collapsed and cold, and *there is uncertainty about the diagnosis*, he at once makes an exploratory incision, thinking it more for the patient's advantage to clear up the diagnosis by surgical interference than by a *post-mortem* investigation. The sense in which the author would use the knife for diagnosis is further shown by the hard hit at the bottom of page 23, which was not dealt without provocation. In publishing these lectures the author has cleared up many obscurities. Could he have published them a few years earlier, some baseless imputations would not have been made, and even the miserable "Battle of Liverpool" might never have been fought.

Before sampling the valuable matter of the work, we may as well dispose of its one blemish in the shape of a plentiful sprinkling of misprints—such as "concensus," "saggital," "ascending colour" (colon ?)—which look all the worse from being set forth on good paper in excellent type. At page 92, "Plate II" is misprinted "Part II;" and the frozen slab referred to as "2 R" is not figured in Plate II, or anywhere else in the present copy.

We may now turn to the matter of the lectures. After remarking that the literature of his subject, and its con-

fusion, are almost equally copious, Mr. Tait proceeds to describe his ætiological theory. It is briefly this:—Desquamative endosalpingitis causes shedding of the ciliated epithelium of the tube, so that the ova are no longer passed out, and the spermatozoa are permitted to pass in; and the obvious consequence of the two elements meeting in the tube is a tubal pregnancy, the sequel of which is a pelvic hæmatocele in one or the other of its two widely different varieties. Passing next to the pathology, the "Scheme of Ectopic Gestations," on page 8, is designed to show at a glance the various pathological forms which these accidents may assume. The Ovarian, or first class, comprises gestations in the actual ovary, in which Mr. Tait does not at present believe. The second class, or Tubal, comprises gestations in any part of the tube except its uterine extremity; in which last position—viz., where the uterine wall clasps the end of the tube, the gestations are formed into a third class under the name of Tubo-uterine, or interstitial. The second, or tubal, is the class of greatest present interest, because in it the confusion occurred of speaking of "ruptured tubal pregnancy" without specifying in which of the two possible directions the tube burst, or which of the two varieties of hæmatocele resulted, varieties which are nearly as different clinically as a carcinoma from a black eye. If the tube be compared to an extended human arm, an ample sleeve may represent the dependent folds of the broad ligament. Now if the rupture occur at the lower part of the tube, it is clear that the fœtal sac will drop into the said sleeve, and (hæmorrhage being limited by the ligament) it may there develop and be removed at term by operation; or it may be absorbed, or it may remain quiescent, either as a lithopædion, or as a mass of adipocere, or as a sac of bones, for any period between three months and fifty-six years! But if, on the other hand, the rupture occur at the top of the tube, the contents are thrown into the peritoneal cavity, where they prove rapidly fatal unless dealt with by abdominal section. How Mr. Lawson Tait, emboldened by Mr. Hallwright, and encouraged by Dr. Dolan, "ran his surgical writ" into an intraperitoneal hæmatocele for the first time is quite an exciting narrative. And as an example of rational pathology passing on to successful treatment, it is one of the most instructive and interesting portions of the lectures. It took three cases to teach the chief lessons; and of these three, two were distressing failures. Mr. Tait places his failures on record with Hippocratic frankness. "*More scilicet magnorum virorum*" is the comment of Celsus on Hippocrates; but one cannot pay that kind of compliment to a man till after he is dead. Mr. Lawson Tait is happily still living. The first case was Mr. Hallwright's, whom Mr. Tait met in consultation; they agreed in the diagnosis of an intraperitoneal ruptured tubal pregnancy; and Mr. Hallwright staggered Mr. Tait by twice requesting him to open the abdomen and remove the ruptured organ; and twice did Mr. Tait decline to do so. "A *post-mortem* examination revealed . . . that if I had tied the broad ligament, and removed the ruptured tube, I should have completely arrested the hæmorrhage; and now I believe that had I done this the patient's life would have been saved." The second case was Dr. Dolan's. "A most striking contrast to this terrible incident will be found in the following case, when, thanks to the ability and firmness of Dr. Dolan of Halifax, I was able save a valuable life." This time Mr. Tait at once opened the abdomen, tied the broad ligament, and removed the pregnancy. The patient is now in a condition of perfect health. This was excellent; but one more lesson had to be learnt before it became quite safe to leave off speaking of "the pitiless termination of extra-uterine pregnancy" (Parry). And this lesson was taught by Mr. Spackman's case. While Mr. Tait was "wasting much time" in cautiously separating adhesions and securing bleeding points, the patient sunk from hæmorrhage. It was a bitter disappointment. He counted on a great triumph, but he scored a great failure. But reflection soon induced the conclusion that the right thing to do in such cases is to separate adhesions rapidly, regardless of bleeding, and make straight for the source of hæmorrhage, the broad ligament; when that is tied at its base, all other matters can be done at leisure. Thus the last lesson was learnt; and thenceforward Mr. Tait's success has been almost uninterrupted. The date of this case is said at page 24 to be "June" 17th, 1883. Was it not *Jan.* 17th? The date is of some historic interest.

It will have been noticed that in Mr. Tait's "Scheme" (page 8) the two ends of the tube are (not without reason) treated very unequally. For while gestation at the tubo-uterine end is elevated into a distinct class, described and figured at page 47, yet gestation at the fimbriated end is included in the tubal class, though recognised by the author at page 13 as a possible subvariety under the name "ovario-tubal." But it is worthy of consideration whether a fimbrian pregnancy, seeing that it might escape from its position without *rupture* of the tube, may not be sufficiently distinct, at least in certain cases, to deserve a class to itself. The cases meant are those in which the pavilion gets glued by adhesions to the surface of the ovary, enclosing what is sometimes called the tubo-ovarian space. For not only is this the space in which Vulliet of Geneva, believes ectopic pregnancies regularly to occur, but also it strikes one that a "pavilion pregnancy" is the very thing to give rise to that rare and singular gestation (with omental or ventral adhesion) described by Mr. Tait at his fifteenth page. By the mere breaking down of the adhesions which bind the pavilion to the ovary, and without actual rupture, and with only a little oozing not to be called hæmorrhage, a fœtal sac might escape into the peritoneal cavity where the placenta would fasten on anything it could touch, and would present the strange appearance of an abdominal gestation with no visible rupture of ligament, or uterus, or tube. The hypothesis of a rupture made and healed again, seems less simple than that of a fimbrian pregnancy breaking the adhesions, and making a quiet escape.

A notice of Mr. Tait's lectures may suitably conclude with some words of Dr. Granville Bantock, published in this journal (Dec. 1st, p. 546). After detailing a case of successful operation in ruptured tubal pregnancy, Dr. Bantock ends thus: "The case carries this lesson, that it behoves general practitioners, who are most likely to be first consulted in such cases, to make themselves acquainted with the symptoms of extra-uterine gestation, in order that, on the occurrence of serious symptoms, they may not overlook such a dangerous complication." General practitioners who wish to take Dr. Bantock's advice, will do well to read Mr. Lawson Tait's lectures.

R. A. CHUDLEIGH.

Plaited Crystal Models. By JOHN GORHAM, M.R.C.S. Eng., etc. London: E. & F. N. Spon.

THERE are few advanced text-books of chemistry without a chapter devoted to crystal forms. It is, however, very safe to assert that the student seldom troubles his head with this branch of the subject; the lettered

diagrams appear to him anything but inviting, and he accordingly shuns them. In mineralogy he is bound to attend to the matter, and here an interest is produced by having cardboard models of the crystals he may be studying, which he makes himself by doubling and bending the prepared cardboard in a definite manner, and then gumming the edges. In the book before us we have a full description of a method of making crystal models, which is a great advance on the old way. Dr. Gorham shows how crystal forms may be made by a simple process of plaiting, and the reader is told how specimens of all the different systems may be obtained. We are bound to admit from the specimen before us, which we have plaited with the three strips provided, that the model is at once elegant and serviceable, and will not, from the manner of building up, be always bursting at the edges, as in the old fashioned gummed models. We are distinctly of opinion that a series of Dr. Gorham's plaited models to illustrate the six systems of crystals ought to be in every science school in the country. Put a boy to plait one of these models, and you make him build a form he is required to remember, and when he sees the result he is delighted. A class of lads may in this way be well grounded in the different crystalline systems, and so be led on to take an intelligent interest in questions of isomorphism and dimorphism, etc. The system of plaiting crystal models also admits of developments which were not possible by the old way. Thus, one may make a plaited model of a bismuth crystal, showing the peculiar pyramidal hollows in the faces, which are also exhibited by crystals of bromide and iodide of potassium; and since it can be so evidently made to show crystal structure, we see no reason why models should not be produced showing the variation of molecular aggregation along the crystal axes to account for various physical phenomena. The book is nicely got up, and contains some fifty-six plates illustrative of the projection of fillets for plaiting, so that the reader may be enabled to prepare any of the crystal forms described in the book. We congratulate Dr. Gorham on having produced a good, useful, and original work.

W. Ackroyd.

Leçons de Gynèiologie Operatoire. Par Vulliet et Lutaud. Paris: J. B. Baillière et Fils.

Until recent years the majority of the diseases peculiar to women were considered rather to belong to the domain of medicine than to that of surgery, but day by day it is found that gynæcological diseases are becoming more amenable to surgical treatment. In the majority of text-books the various diseases are described, and the methods of treatment are indicated, but too little instruction is afforded as to the *modus operandi* of various surgical procedures. Drs. Vulliet and Lutaud, in their joint treatise, deal with gynæcology from an exclusively operative point of view, and we know of no other work which gives so clear and vivid a description of the various details which are necessary to be observed, in order that gynæcological operations may be attended with good results. The book is illustrated with 180 original drawings by M. Bourcart, and although some of the drawings may appear to be wanting in finish, yet the object of the illustration is invariably realised, and the idea which the authors wish to convey is never in doubt. All historical researches are excluded from the general plan of the work, and the reader is presumed to be familiar with the use of the speculum, bi-manual examination, and the elementary rules for conducting a gynæcological examination. All the operations which require laparotomy are omitted, and the work is essentially a manual of operative procedure *per vaginam*. The first lecture chiefly deals with antisepticism, as employed for uterine and vaginal disinfection, and the second describes in detail the most favourable positions for examination and for operation. The remaining twenty-one lectures are almost exclusively devoted to operative work. The conditions which permit or contra-indicate the drawing down or artificial prolapsus of the uterus, to facilitate plastic and other operations, are dealt with in a concise and satisfactory manner. The chapters devoted to curetting the uterus, to Emmet's operation, and to genito-urinary fistulas, are all eminently instructive, and form a safe guide for workers in this field. The treatment of uterine fibromas is, according to the plan of the work, restricted to such methods as are applicable *per vaginam*. In the employment of electricity, the authors are scarcely disciples of Apostoli; they consider that favourable results as often follow faradisation as galvanisation, and their plan is to place one of the electrodes on the neck of womb, and the other on the abdomen; the introduction of one of the poles within the cavity of the uterus is held to be useless, and they never attempt to produce caustic effects by puncturing the uterus with an incandescent electrode; if it is necessary to destroy or disorganise the substance, it is better done by means of a bistoury after dilatation. The chapter on massage (introduced for pelvic affections by Thüre Brand) brings forward a method of treatment which is capable of doing good in a certain class of cases where no inflammatory mischief exists; the practice was at one time considered indecent and brutal, and we certainly think that it possesses some objectionable features. It may be useful in promoting the absorption of old adhesions, and the authority of Schultze, of Iena, is justly entitled to great weight; nevertheless, we think great evils might result from the indiscriminate practice of massage by the male on the female sex, and when it is thought likely to prove beneficial, we should be inclined to call in to our assistance a skilled female *masseuse*.

The lectures on the surgical treatment of cancer are excellent, and will well repay attentive study. The lectures on the operative treatment of uterine displacements, including the use of pessaries, leave little to be desired. Sims', Schrœder's, Alquié Alexander's, and other operations are described, as well as what the authors term laparo-hysterorraphy, or the stitching of the uterus to the abdominal walls. The operations for the repair of ruptured perineum are well described, and a just tribute is paid to Mr. Lawson Tait, of whose skill as an operator, the authors evidently entertain the highest opinion. The four last lectures deal with sterility, and especially with the conditions capable of removal by operative measures. The question of artificial fecundation is one which would hardly be entertained by English medical men, nevertheless, it has been practised successfully in about ten per cent. of the patients who have been willing to submit to this repulsive treatment. Love of offspring and maternal instincts must be unusually strong before any woman would consent to the supervision of her conjugal relations by a medical man; and we believe that every pure-minded woman would consider sterility far preferable to the degrading measures which alone render artificial fecundation possible.

Taking the work of Drs. Vulliet and Lutaud as a whole, we cannot but think that it is the best work of its kind yet

published; there is no padding; all is clear, concise, and carefully reasoned; the student will find therein all that is needful he should know about operative gynæcology, and the expert will find a careful *resumé* of the most recent and important measures which may be prudently adopted in suitable cases. H. R. HATHERLY.

L'Enseignement et L'Organisation de L'Art Dentaire aux Etats Unis. By Dr. KUHN. Paris: Octave Doin.

THE report addressed by Dr. Kuhn to the Minister of Public Instruction gives a most exhaustive account of the training of dentists in the United States, and of the laws which bear upon the practice of dental surgery in each state. Although the bulk of this work of 300 pages is devoted to America, the systems in vogue in England, France, Germany, Austria, Spain, Belgium, etc., are all referred to sufficiently for purposes of comparison. The colleges of dental surgery of Baltimore, Ohio, Transylvania, New York, Philadelphia, Pennsylvania, Missouri, New Orleans, Harvard, Boston, Maryland, etc., are all described, and the course of instruction is fully detailed. There can be little doubt that the American system, both as regards instruction and examination, is calculated to weed out all incompetent practitioners. One point is brought out in strong relief, that is the essentially practical nature of the examinations. A candidate for the diploma of Doctor of Dental Surgery is expected to present a written *thesis* on some subject which bears upon the theory and practice of dentistry; he must treat a patient requiring some recognised dental operation, and the patient must be submitted to the professor of operative dentistry; he must also adapt artificial teeth, and present the patient to the examiner; he must also prepare a pathological specimen for the museum, and finally he must undergo an examination before the board of instruction, who, if they pronounce him capable, recommend him to the Administrative Council for a diploma. The fee for the full course of instruction varies in different colleges—at Philadelphia it is £21; at California £59. The examination fee is the same everywhere, £6.

The laws affecting the practice of dental surgery vary much in different states, but on the whole the American dentist has no cause to complain that he is not adequately protected in the exercise of his profession. In every state penalties of from ten to three hundred dollars are inflicted for illegal practice, except in that of New York, where punishment is only awarded to those who usurp the title of dental surgeon when not duly qualified. In some of the states extraction is permissible for all; in others medical men only are authorised to extract teeth, a privilege not extended to the general public. In some states dental operations by medical men are allowed; in others medical men who have no dental diploma are not allowed to perform dental operations. Every dentist, whatever the nature of his diploma, is required to take out a license to practise from the recognised authority of each particular state, and a fee, varying from five to thirty dollars, is usually charged. In a few of the states no fee is charged. In ten states the exercise of the practice of dental surgery is restricted absolutely to dentists; in three states medical men may practise; in six, medical men are only permitted to extract teeth, and in ten states extraction is not restricted to either dentists or medical men. In thirty-eight states of the Union the dental art is recognised and organised. In every state save New York irregular practice is illegal, and in every state dental surgery is considered as separate and distinct from the practice of medicine. Foreign degrees can for the most part be recognised without passing any additional examination.

Dr. Kuhn argues very clearly that the dental art is, and should be kept, separate and distinct from other branches of surgery. It is not possible to disassociate it from medical practice entirely, inasmuch as it is the application of several different sciences, of which, perhaps, it borrows most extensively for its methods from medicine, which may be considered the fundamental basis of the dental art. To those who are interested in the practice of dentistry, and who desire an insight into the regulations concerning it which prevail in the United States, regulations which have no doubt contributed to raise the standard of American skill to its present high-level, we would strongly recommend a perusal of Dr. Kuhn's treatise. The report is a valuable one from every point of view: it is printed in large type, on thick paper, and is further embellished with a few good illustrations. H. R. HATHERLY.

The Place of Saccharin in Pharmacy. By Professor ATTFIELD, F.R.S., etc. pp. 16. 1889.—"Saccharin: A Vindication." London, 1889.

PROFESSOR ATTFIELD'S reputation being co-extensive with British pharmaceutical science, the pamphlet before us is accepted as a confirmation of the "vindication" of saccharin, by Messrs. Wilson, Salamon & Co., which appeared in our last number, and has been separately published by that firm in a more extended form. From these publications it has now become, beyond contradiction, the received opinion that saccharin is a most valuable adjuvant in the treatment of diabetes. Dr. Pavy, Dr. Stevenson, Dr. Lauder Brunton, Dr. John Dougall, Dr. Little, Dr. Bey, and other medical names are given as testifying to the value of saccharin, and its entire freedom from the injurious action by which it has been discredited. We do not, in a question of science, bow to authority, but readily accept as equivalent to fact the experience stated by observers so well known and so highly esteemed. The unanimous verdict upon the use of saccharin is that it becomes quickly absorbed, and is rapidly eliminated by the kidneys in an unchanged condition; that it cannot therefore exert any hurtful influence upon digestion. On the contrary it has been shown to have exercised a direct curative influence in cases of diabetes. The further therapeutic efforts of this substance remain to be developed. Dr. Attfield gives formulæ for the exhibition of saccharin:—"Most of the large number of Galenical preparations, as commonly ordered by physicians, and now made with sugar, would be prepared with saccharin (formulæ given) and would be set forth in prescriptions under distinctive names—*e.g.*, mist. cretic *sacc.*; pulv. glycyrrh. co. *sacc.* concent.; conf. sennæ *sacc.* concent.; etc.

Concerning incompatibles. Dr. Attfield observes:—"Saccharin is a tolerably indifferent substance. It is unaffected by the fluids of the body, acid, or otherwise, for it has been proved to pass through the system unchanged. Fusion with caustic alkali gives a salicylate, hence prolonged contact with strong alkalies is probably undesirable; and, obviously, acids would precipitate saccharin itself from a strong, though not from a weak, solution of a soluble sarrachinate, weak in soluble saccharin; but saccharin is quite unaffected by the ordinary materials used in medicine." Respecting nomenclature. Dr. Attfield remarks, with

justice, that it is to be regretted that the name saccharine was given to the substance under consideration, as the word is already in common use in trade for various kinds of sugar. *Saccharum*, the Latin word, being generally employed in various forms, an entirely new word would have been preferable. Dr. Attfield suggests *glukusin* (γλυκυς, sweet), not glucosin or glucosine. A still better name, suggested by Dr. Attfield, would be *neosaccharin*, "which would have prevented the contraction in prescriptions being identical with that for sugar." In the Galenical prescription given by Dr. Attfield, the names appended may prevent the mistake. Upwards of thirty formulæ are contributed by the combined experience of several pharmacists, or have been contrived by the author for the present purpose. The general principle followed in compiling these has been to replace the sweetness of sugar by the sweetness of saccharin, without altering the strength of the preparation. For the details of these formulæ, the pamphlet of Dr. Attfield must be consulted. The commercial price of saccharin is high, but comparing its sweetening power with that of sugar it cannot be regarded as otherwise than low. W. B. Kesteven, M.D.

Section Cutting and Staining. By Walter S. Coleman, M.B. Lond., formerly Assistant to the Professor of Pathology in the University of Edinburgh. London: H. K. Lewis, Gower-street. 1888.

Of the many practical guides that have appeared in recent years this little book will be found to be one of the most useful. It is just what the student, or the practitioner who dreads tackling a large work on the subject, requires. We are told what kind of apparatus to get, and how to get it good and cheap, which the author rightly deems to be often of great moment. Moreover, we are told how to keep our specimens, how to make some of our apparatus, and some of our solutions. Various modifications of Cathcart's microtome are recommended—*e.g.*, one to use with Swift's plough and Frazer's for celloidin embedded objects. William's ice freezing, and Schanze's instrument, are both figured and described. If one took the title of the book literally, hardening, decalcifying, and section mounting would have no place, but such is not the case, all are included. The latter part of the work is devoted to directions for preparing individual tissues. A thorough mastery of the normal appearances of tissues and organs is insisted upon, and full directions are given. The various pathological degenerations and tumours are dealt with. We can recommend Dr. Coleman's little book to all who are beginning to work at the subject. C. A.

Epitome of Diseases and Injuries of the Ear, with a Chapter on Naso-Pharyngeal Diseases causing Deafness. By W. R. H. Stewart, F.R.C.S., L.R.C.P. Edin., etc., Aural Surgeon to the Great Northern Central Hospital, etc. London: H. K. Lewis, 136, Gower-street, W.C.

Although the utility of small treatises on the ear is often questioned, we welcome the little work by Mr. Stewart as a distinct addition to otology. In his preface he plainly states that the book is in no way intended to take the place of the larger works on the ear, but that it should be an aid to the student in his clinical work, and a convenient guide to the busy general practitioner; and we have but little doubt that it will fulfil the object for which it has been written. The appearance of several books lately on ear disease, may be taken as a sign of the times, and all good works, which throw any light upon the pathological conditions to be met with in the organs of hearing, and the treatment to be adopted, will add to the interest now being more universally taken in this important branch of medicine. We are also pleased to find that it is not tagged on to a treatise on diseases of the eye, for in our opinion the association of the ear with the eye, so often met with in our special hospitals, has been the main hindrance to the proper development of otology in this country. Within a space of 113 pages, Mr. Stewart gives a fairly concise account of the principal diseases of the ear, with their causes, symptoms, prognosis, and treatment. The chapter treating on cerumen and foreign bodies in the external meatus is very well written. We are pleased to see that he deprecates strongly the use, by unpractised hands, of instrumental treatment other than syringing, in the removal of cerumen and foreign bodies in the meatus. In his remarks on the treatment of ivory exostosis, the entire omission of all mention of the use of the chisel and mallet, which, in our hands, is preferable to the American dental drill, is an error which should not find a place in a second edition. George Stone.

A Handbook of Surface Anatomy and Landmarks. By Bertram C. A. Windle, M.A., M.D. Dub., Professor of Anatomy, Queen's College, Birmingham. London: H. K. Lewis. 1888.

In this little book, which lays no claims to originality, Dr. Windle deals with the study of anatomy as a teacher familiar with the wants of the practical student, and he has succeeded in producing a work that presents the results of many laborious investigations in a systematic and attractive form. The various landmarks and surface markings of the body are fully described, and directions are given for mapping out the position of the internal organs; the digital examination of the various orifices is detailed, and hints are given for the performance of simple operations, such as passing the catheter and paracentesis thoracis. The rules given are explicit, and such as are likely to be retained in the memory, and are not clogged by unnecessary details. The section on the relations of the scalp to the brain and other structures will be found particularly valuable. The occurrence of a few inaccuracies is incidental to the first edition of a work of this kind; in the present, for instance, the rule for finding the fissure of Rolando is wrongly given in the text, though the diagram is correct, and the membranous portion of the urethra is wrongly stated to be the most frequent seat of stricture. On the whole Dr. Windle is to be congratulated on having produced a book which successfully treats of human anatomy from a highly important standpoint, and which forms a valuable addition to the literature of the dissecting room. It may be safely recommended to all students and practitioners who wish to reap the practical fruits of their anatomical studies, and it will be especially useful to students preparing for examination. T. R. Bradshaw, M.D.

A Handbook of Therapeutics. By Sydney Ringer, M.D., F.R.S. Twelfth edition. London: H. K. Lewis.

Dr. Ringer's work has met with almost unprecedented success, this being achieved by its own absolute merit. The busy practitioner has found out its merits, and there are few libraries from which it is absent. The latest edition has been thoroughly revised and brought down to date, and we anticipate that it will soon be exhausted, and a new edition required. We need not enter into an analysis of its contents,

The Provincial Medical Journal,

MARCH, 1889.

IS IT an indication of increasing respect for the profession that the doctor is becoming a more frequent character in novels, and that he is even appearing on the stage, and that, as a rule, the portraiture is drawn from the best side, the doctor's work being presented in a lovable light, as in the following description from a novel entitled "Dr. BREEN'S Practice" (by HOWELLS)? Dr. MULBRIDGE is thus described at the bedside of a female patient: "He was incredibly soft in all his movements, and perfectly kind, without being in any moment unprofitably sympathetic: he knew when to listen and when not to listen; to learn everything from the quivering bundle of nerves before him without seeming to have learnt anything alarming: he smiled when it would do her good to be laughed at, and treated her with such grave respect that she could not feel herself trifled with or remember afterwards any point of neglect." This is a very different description from the rough-handed surgeon of TENNYSON.

In a very interesting address contributed to the Polyclinic Society of Philadelphia, Dr. Ross M. BUNTING has collected together from a number of novels the descriptions given of our profession, and it would certainly appear that the modern novelist writer has very much improved in his conception of our profession, from such older writers as LE SAGE, MOLLIERE, and STERNE. "Dr. SANGRADO" is historical, and much better known to most readers than the "Dr. SLOP" of LAURENCE STERNE, though we consider that STERNE'S portraiture is a much better work of art than the "SANGRADO." The description of "Dr. SLOP" and his forceps is an inimitable piece of writing, though it is marred by the faults which disfigure STERNE'S works. Dr. BUNTING reminds us that we have in "GIDEON GRAY" (of SCOTT) a doctor in whom our profession may feel a just pride. He says that he is a true picture of the country doctors in Scotland of that time, giving as an instance the name of Dr. ADAMS, the translator of "PAULUS ÆGENITA" and "HIPPOCRATES." In "Dr. ANTONIO," "Dr. THORNE," "Dr. HERBEAU," "The Country Doctor," "The Doctor of Dene," we have also pleasant sketches of professional *confrères*. We agree with Dr. BUNTING'S statement that to GEORGE ELIOT must be awarded the credit of having given the best delineation of a doctor in romance. "LYDGATE carried to his studies in London, Edinburgh, and Paris the conviction that the medical profession as it might be was the finest in the world; representing the most perfect interchange between science and art; offering the most direct alliance between intellectual conquest and the social good."

LYDGATE, with his high ambitions, was, however, weighted down by his wife, and the accomplishment of his aim was frustrated, though he became a successful doctor in a sense. OLIVER WENDELL HOLMES has described for us a shrewd old-fashioned practitioner in his "ELSIE VENNER," a remarkable book, which has as its basis the subject of maternal influence. The old doctor makes some shrewd observations, amongst which are the following. He confesses he does not read much, but he makes this the excuse: "When a man that's once started right lives amongst sick folks for five and thirty years as I've done, if he has not got a library of five and thirty volumes bound up in his head, at the end of that time, he had better stop driving round and sell his horse and sulky." Medical men are often accused of being indifferent to religion, and of being Atheists. The old doctor in this book has a conversation with the clergyman on this point, and he tells the clergyman that "GOD opens one book to physicians that a good many of you don't know much about—the book of life. That is none of your dirty folios, with black letters, between pasteboard and leather, but it is printed in bright red type, and the binding of it is warm and tender to every touch. They reverence that book as one of the ALMIGHTY'S infallible revelations. They will insist on reading to you lessons out of it, whether you call them names or not. These will always be lessons of charity." In many novels we find good descriptions of lady doctors, as in "Doctor ZAY," by Miss PHELPS. The heroine says, in reference to the profession: "It is unmatched, I believe. Even the clergy have a poor one beside us. We stand at an eternal confessional, in which the chances of moral escape or evasion are reduced to a minimum. It is holding human hearts to count their beats. When you count the contest between life and death you have a position unique in human relations." Women doctors figure in a novel by SARAH ORNE JEWELL, and in "The Woman Hater," by CHARLES READE. The heroine in the former novel says, in favour of the study of medicine by women: "I believe that GOD has given me a fitness for it, and that I could never do anything else half so well. I do not wish to be married, nor do I think it right that I should be. If I have good reasons against it, would you have me bury the talent GOD has given me, and choke down the prayer every morning that I may do this work lovingly and well? I will not attempt to say that the study of medicine is a proper vocation for women, only that I believe more and more every year that it is the proper study for me. It certainly cannot be the proper vocation for all women to bring up children, so many of them are dead failures at it; and I don't see why all girls should be thought failures who do not marry. I don't believe that half those who do marry have any real right to it, at least until people use common sense as much in that most important decision as in lesser ones. The preservation of the race is no longer the only important question; the welfare of the individual will be considered more and more. The simple fact that there is a majority of women in any centre of civilization means that some are set apart by nature for other uses and conditions than marriage."

Dr. Rhoda Gale, in "The Woman Hater," makes a strong point in the following paragraph :

To open all hospitals and infirmaries to matriculated students, without any respect of sex, as they are already open by shameless partiality and transparent greed to unmatriculated women, provided they confine their ambition to the most repulsive and unfeminine part of medicine, the nursing of both sexes and laying out of corpses—I say that to open the study and practice of medicine to women folk under the infallible safeguard of a stiff public examination, will be to rise in respect to human rights to the level of European nations who do not brag about just freedom half as loud as we do.

Dr. Bunting has not by any means exhausted the number of novels in which medical men figure. He says that it is a matter of regret that the self-sacrificing spirit of the physician is rarely appreciated, and that though we have some descriptions, yet the examples of medical heroism as shown in the plague of Marseilles, the famine fever in Ireland, and the yellow fever in America, would furnish material enough for scores of romances. We believe that we are within measurable distance of what Dr. Bunting calls medicated novels, and the fear now is that they may be rather overdone, especially in regard to physiology and pathology.

The saccharin controversy, we believe, is now finished, and the atmosphere is cleared, the result being a distinct gain and impetus to the use of the agent. The harmlessness of saccharin, even when pushed to its highest point rests upon such a solid basis of experience, that it would be folly now to dispute it. The pamphlet issued by Professor Attfield, F.R.S., one of the editors of "British Pharmacopœia," assures for saccharin a place in pharmacy from which it will be difficult to displace it. The numerous formulæ he gives open out a new development. He shows us it can be used for gargles, mixtures, emulsions, powders, using in place of a solution of sugar an equal volume of a solution of saccharin, which he calls solutio saccharini simplex, and which has the same degree of sweetness as the syrup of the "British Pharmacopœia," and therefore can be prescribed in exactly similar quantities. Saccharin at present may seem to be dear, but when compared with sugar in proportion to bulk, it will not be found to be so. It has already considerably lowered in price, and there is every probability that it will reach a lower figure, thereby following the law which seems to regulate all new products. We thoroughly agree with Professor Attfield in his lament, that such a name should have been given to this complex body, and for a time some little confusion may arise between saccharum and saccharinum, especially when an abbreviation is used. When saccharin becomes incorporated in the "British Pharmacopœia" it can be re-christened, so as to obviate any confusion, the present synonym being retained. The evidence of the best therapeutists is to the effect—

1. That saccharin is quite innocuous when taken in quantities, largely exceeding what would be taken in any ordinary dietary.

2. That it does not interfere with, or impede the digestive properties when taken in any practicable quantity, and that it may be taken for an extended period without interfering with the digestive and bodily functions.

Hence there is no reason to limit its use, and as it may be usefully employed in medicine as a sweetener, so it may be used for culinary purposes, to give dishes a more agreeable taste. When we consider the large number who are not allowed to use sugar, we cannot but see what a boon this new product will be, and how much we can be assisted in having at our disposal a perfectly harmless substance as a substitute for sugar. We publish in another column a review on two pamphlets which have been sent to us, from which our readers can learn more as to the nature of the saccharin controversy. In the last issue of the journal appeared a long and exhaustive letter from Mr. Salamon, which very succinctly exposed the origin of the outcry which was raised against this agent.

We underated the influence the sugar question had in the exclusion from France of saccharin as a saleable commodity, on the alleged ground of noxiousness. The *Journal de Médicine de Paris*, of February 10th, is outspoken on this point. The editor says :—"It is known that the French Government, perplexed without doubt by the consequences which would ensue to the native industry by the consumption of saccharin, interdicted the entry of this substance into France. We should not think of criticising the measure were it not based on an erroneous fact—the noxiousness of saccharin. Now, M. Dujardin Beaumetz, and many therapeutists, were at first its warmest partisans before Government comprehended the necessity of intervicting its employment. The French State has, we are convinced, serious reasons to fear the substitution of saccharine for sugar, since we draw more than two hundred millions each year from the tax on sugar. But we still think she must take, against this, fiscal measures, based on budgetry considerations and *not* on scientific considerations, which are not seriously regarded in any country. The Government of Holland occupied itself with the possible dangers the habitual employment of saccharine might have upon the public health, and asked the advice of different provincial sanitary bodies, who gave contradictory opinions, though favourable to the use of this new product. The Upper Council of Health, however, after an enquiry, declared that, in view of hygienics, there was no ground to prohibit the alimentary employment of saccharine. The Governments of England, America, and Germany, which have seriously studied this question, consider it not only as an inoffensive condiment, but as useful for the preservation of foods on account of its eminently antiseptic properties." This open declaration in a well-known French journal should settle the question.

At a meeting of the Chemists' Assistants' Association, London, January 24th, Mr. A. Campbell Stark read a very suggestive paper on the subject of "Trade Protection : its present relation to Pharmacy ;" and we venture to offer a

few remarks on the paper, recognising that medicine and pharmacy are in a great measure associated, and that what interests or affects the chemist should interest us.

The pharmaceutist of the present day is suffering from the effects of over-competition in his own trade—hence the cutting down of prices—and from the still more galling competition of those outside his trade, who sell also at lower prices the patent medicines, the soaps, perfumery, and other toilet articles by which the chemist supplemented his income. It cannot be for one moment pretended that the sale of toilet requisites, or the endless odds and ends in the shape of soaps, powders, and foods, belongs to the chemist as a right, or has anything whatever to do with the proper *rôle* of the pharmaceutical chemist; so that protection for the chemist, so far as the sale of such articles is concerned, cannot be reasonably enforced. We are not aware that any sensible chemists do claim, as their prerogative, the right to such sales; but we mention this point to clear the ground. We do admit that the chemist has very materially suffered from the competition of stores and grocers in the sale of many articles, on which formerly large profits were made. Where the legislature may legitimately interfere for the protection of the pure chemist we think we can point out. The chemist owes his existence to a desire on the part of the Government to protect the people—in the first place, providing for their use qualified dispensers; and, again, restricting the sale of poisons, so that human life might not be taken away by placing in the hands of the general traders the means by which the general public could accomplish poisoning. The legislature imposes great obligations on the part of those who enter on the duties of a chemist: it has framed a curriculum, followed by an examination, penalties being enforced, so as to insure that the public may be faithfully served. The pharmaceutical chemist occupies a very different social position from other traders. His examinations and his associations stamp him as being superior to them. The legislature, however, does not treat him fairly, after requiring so much from him. It allows medicines to be sold by the qualified and unqualified; and here we agree with what is a very old professional saying—*that all medicines are poisons;* and as the Government has made a distinction by only allowing a certain number of medicines, known poisons, to be sold only by the chemist, it should go farther, and protect the chemist by forbidding all but members of the Pharmaceutical Society from selling medicines. Free trade in drugs is not conducive to the best interests of the people; and though we are a free trading people, yet we may be permitted, when occasion requires, to draw the line at a certain point, and we should certainly draw it at the sale of medicine. If the pharmacist had the absolute monopoly of the sale of medicine, and the dispensing of it, would he be content? Would it be sufficient for him to make a living by? for, after all that is the great question which is at issue. Would those chemists who now sell whisky, tea, soap, sugar, and toilet requisites, give up the sale of these articles? If they continued such sales after securing a monopoly, they would very soon stir up opposition from other traders, upon whose business they were encroaching. We believe the chemist would be very much elevated in social status and influence if the Government gave him the monopoly of the sale of medicines; but if the Government added the proviso that the chemist should not, under a penalty, sell articles such as those above named, would the monopoly be worth securing? This is a question for chemists to answer.

The dispensing of medicines by medical men is, we believe, somewhat on the decline. We cannot at present enter into the very large question as to whether medical men should give up dispensing; but at some future time we shall take up this part of the question, and examine the *pros* and *cons*.

WE have received from the editors of the *Australasian Medical Gazette* a copy of an article by Mr. G. R. MACMULLEN, M.A., LL.D., exposing the danger of sea travelling with a consumptive cabin companion. Mr. MACMULLEN writes as a layman to laymen, but he is evidently well informed on the subject on which he writes, and the danger he points out is a real one. He draws a picture, true to life, of our ocean bound steamers, where the traveller in perfect health, and in full anticipation of a pleasant voyage, after securing his birth, has his dream rudely broken, as soon as it is found out that his companion is consumptive. He will have for a certain time to be associated with him, and independent altogether of the unpleasant incidental surroundings—the coughing, the expectoration—he will have to run a real danger if our modern views of the nature of phthisis be true. The modern view is really a return to the old view. In England for years we abandoned the idea that consumption was in any way communicable, while many nations clung tenaciously to the belief that phthisis was highly communicable, and, in consequence of this belief, they took care to segregate consumptives, observing at the same time strict sanitary precautions as regards them. Thus sleeping with consumptives was forbidden, whilst their clothing and bedding were even regarded as a possible means of conveying the disease. We have for years been acting in absolute disregard of the general welfare, by the manner in which we have ordered our consumptives from one country to another, thereby giving a wider geographical distribution to the disease, and exposing the healthy to what we may call infection. The time is now come for us to review our position; even though we have to be taught a lesson by a layman, we should not be above receiving it. We believe that Mr. MACMULLEN'S arguments are unanswerable. What we have to do concerns the individual and the community. We must consider under what conditions the individual consumptive may travel, and what precautions should be taken by the consumptive traveller. Whilst then some provision must be made for the benefit of those who are consumptive, and who are ordered a sea voyage, at the same time the interests of the

healthy must be conserved. This might be brought about by the adoption of Mr. Macmullen's suggestions:—

"Now, as regards a remedy for this state of affairs, I would suggest the following, which I do not think unreasonable, though perhaps capable of amendment. In the first place, all intending passengers should, on booking, be able to produce to the shipping agents (who should under penalty insist on its production) a medical certificate stating that the intending passenger is in good health, or if not so, the nature of his or her ailment. Secondly, the medical officer in charge of the ship should have the power to remove a passenger into the ship's hospital, which, in view of such contingency, should be properly fitted for the reception of patients. Of course, when a passenger occupies a whole cabin the rules should be relaxed. This would be no hardship to the patient, but a positive benefit, and would result in general convenience and satisfaction. The certificate might be given by a physician appointed by the shipping company, or by the usual medical attendant of the intending passenger. I feel convinced that if some such regulations were in force, travelling by sea would receive an additional attraction in the shape of comparative immunity from the dangers of infectious disease, which is far from being the case at present, especially as regards the particular complaint above discussed. There may be difficulties in the way of bringing about such conditions, but some regulations of the sort should be instituted, and I shall be content if these lines fall under the eye of any whose ideas on the subject may agree with my own, and whose influence and inclination may enable them to assist in procuring a much-needed reform."

Annotations.

"Forsan et hæc olim meminisse juvabit."

THE HANDWASHING CONTROVERSY.

It has gone round the world, and endless are the suggestions made, and the prescriptions devised, in order to secure clean hands. We hardly believed it possible that so much nonsense could be written on such a subject, and it only shows us that it is not the lay press which has its big gooseberries, etc. One result will be no doubt that some will wash their hands who have never before indulged in the practice.

THE VOLUNTEER MEDICAL SERVICE.

As the result of the recent deliberations of the War Office Committee, the following recommendations have been adopted:—1. The whole of the volunteer medical officers, both regimental and those attached to the volunteer medical staff corps, are now classified according to rank and date of commission under a separate heading in the army list. 2. All acting-surgeons in possession of a certificate of proficiency can, upon recommendation by commanding officers, be commissioned to the rank of surgeon. 3. Volunteer surgeons can be promoted after fifteen years' service to the substantative rank of surgeon-major. The development of the Volunteer Medical Service has been slow, but it has been sure and progressive, and the recent changes will give great satisfaction.

FEES FOR ATTENDANCE ON INDIAN PRINCES.

The Governor of India has issued an order that when a medical officer is permitted to attend a native prince, the fee to be paid for such attendance to be settled by Government, to whom the amount of the fee proposed should be reported by the political agent for sanction before it is communicated to the medical officer concerned. This appears to us as if the Government of India were going a little too far. The King of the Belgians, we believe, presented Sir Henry Thompson with a cheque of four figures, in appreciation of the relief he afforded him. Had Sir Henry been in India, and in the Indian Service, and had he been allowed to give his services, the sum of four figures might have been reduced to one of two by the arbitrary action of some officials, who themselves do not like to pay doctors' bills. If medical officers are allowed to attend native princes, and if they give valuable services, we fail to see why their fees should be limited.

MEDICAL MEN IN THE COUNTY COUNCILS.

The following medical men, amongst others, have been elected on the County Councils:—Dr. F. E. Ryott (Berkshire), Dr. Walter Harley (Staffordshire), Dr. G. A. Jeffery (Sussex) Dr. G. H. Anderson (Lofthouse Division, Yorkshire), Dr. J. Glen (Normanby Division, Yorkshire), Dr. G. W. Richards (Worcestershire), Dr. Herbert Hayes (Newington), Dr. Allan McLean (Portland), Dr. Rowland Williams (Holyhead), Dr. Edward (Mold, Flintshire), Dr. T. H. Redwood (Rhymney), Dr. S. H. Steele (Abertillery), Dr. G. Jeafferson (Framlingham), Dr. Turle (Finchley), Dr. Hogg and Dr. Hodgson (Crewe, Cheshire), Dr. R. Thompson (Hampshire), Dr. W. L. Winterbottom (Bridgwater, Somerset), Dr. Johnson (Wiltshire). In Merionethshire the election has resulted in the election of five members of the profession.

QUACKS AND QUACKERY AT THE ANTIPODES.

The profession at the antipodes are troubled even worse than we are here by the illegal practitioners of medicine. Though there is a law regulating the practice of medicine, unfortunately, the Chief Secretary of Victoria favours the quacks, and he will not allow the police to initiate proceedings against the unqualified. The Australian *Medical Gazette* very truly says on this point: "The existence of a Government is only justified by the protection it affords the public against all preventable evils, one of the greatest of which is the lax administration of a law enacted with the object of preventing persons, not having facilities for minute enquiry, from being imposed on by the misrepresentations of scoundrels."

MEDICAL ACTIONS.

After four days' trial, brought by Mr. C. Egerton Jennings against Dr. Herbert Snow, the case ended in a verdict of £10 for the plaintiff. From every aspect of this case it is regretable that it was brought into a court. The public appear to like actions of this kind, as the court was crowded during the hearing, and no doubt they were very much edified by the divergence of opinion on some of the points in dispute. It is a pity we have not some court of honour to which matters of this kind could be referred. Another action, remarkable in its way, too, was brought by a practitioner against the Medical Council for erasure of name. This resulted in a verdict for the Medical Council. On the morning after this trial a letter appeared in the London *Daily News*, signed J. Clifford Allbutt. This letter we are assured was a forgery. Surely there must be some method of punishing forgers.

ASSOCIATION FOR THE DEAF.

The members and friends met in the Glasgow Ear Institution, Buchanan-street, on the 6th inst., when Dr. J. Erskine presided, and explained that arrangements had now been completed for giving systematic instruction to the members in lip-reading or the German method of oral communication. Hitherto deaf or deaf-and-dumb children only have been taught lip-reading and articulation. The Association for the Deaf, therefore, whose members are all adults, and retain their faculty of speech, have initiated the teaching of the oral method to a class of people for whom it is especially suited. They are in a position to acquire it readily, and derive much practical benefit, as such a method of communication will bring them into much closer and freer relation with their hearing neighbours than the use of digital signs. The duties of teaching the members of the association have been undertaken by Miss Robertson, whose work, under the Govan School Board, is being attended with much success. The class, it may be mentioned, received high commendation from the Royal Commission on the Blind, Deaf, and Dumb, on the occasion of their recent visit. The twenty-third annual gathering of the deaf and dumb took place under the presidency of Lord Roseberry.

PATENT MEDICINES.

The profession has been exercised from time to time as to whether it should use patent medicines. It does use them as a matter of fact—witness antipyrine, vinolia, etc. The profession may take its cue from the *Lancet* and *British Medical Journal* advertisement sheets. Patent medicines are evidently quite proper. Both journals claim to stand in the position of guides to the profession, and consequently their advertisement sheets stand in the same light. The profession may use any medicine advertised in the above-mentioned columns. Take away the *patent* medicines, where would the advertisement sheets be?

PROTECTION IN THE STATES.

The profession in the States are crying out for protection against the foreign diplomates, who invade her peaceful and dollar-bearing shores, greatly to the injury of the native. The American doctor has been much vilified. Now it appears from such veracious journals as the *New York Record*, that it is the foreigner who brings such discredit on America, and as that paper states "that English medical men are not gentlemen," we must bow down before this dictum. The specimens who went to Dr. Billing's Congress must not have been up to standard.

THE MEDICAL SICK AND BENEFIT SOCIETY.

The above society is steadily accumulating capital, besides liberally disbursing its funds to all sick or disabled members. We may shortly expect a quinquennial report and valuation, which will give information—unique of its kind—on the healthiness of the profession. New members are steadily entering, and the position of affairs is most gratifying. Young practitioners should write to Mr. Radley, 26, Wynne-road, Brixton.

THE BRITISH GYNÆCOLOGICAL SOCIETY.

This society is established on a broader and more liberal basis than any other London society. It actually realised that its presidents might live in the provinces, and carried out its conviction by electing Mr. Lawson Tait, and by the recent election of Dr. Macan to the presidential chair. It is a progressive society, and we therefore direct the attention of provincial practitioners to it. Its transactions are worth the subscription.

CERTIFYING FACTORY SURGEONS.

The position of certifying factory surgeons is in danger. This has been in some cases a lucrative and easy office, especially where large districts were held, though of late years it has not been so pecuniarily advantageous. Mill-owners state that the factory surgeon is not required, certificates for school attendance being sufficient to indicate age of children. We can hardly admit this plea. The factory surgeon should have something more to do than pronounce on the age of the child. He should testify as to the child's fitness for work.

THE RESORT OF THE WELL-TO-DO.

The hospital is now the resort of the well-to-do. Originally intended for the poor, the hospital has degenerated. The poor have to go to the Union Infirmary, or the Parish Dispensary, their place being usurped by the subscribers, who give their three or four shillings a year, at mill yards, clubs, etc. Some of our old charities, originally endowed for the benefit of the necessitous poor, have been seized on by the better-to-do classes. The hospitals are sharing the same fate. We do not wonder at the outcry raised by the profession, or at its poverty.

THE KNIFE *VERSUS* ELECTRICITY.

We learn from the *Medical Register*, Philadelphia, that the quiet valley of the Ohio, the whilom home of Aaron Burr, has been surprised by a challenge. This is issued by Dr. R. Stanbury Sutton, of Pittsburgh, to Dr. E. S. McKee, of Cincinnati. Dr. McKee made a visit to Paris, and returned an apostle of Apostoli, the father of the treatment of fibroid tumours of the uterus by electricity in strong and accurately-measured doses. On several occasions since his return he has written concerning this subject, and at a recent meeting of the Cincinnati Academy of Medicine spoke of it as an "efficient substitute for the knife, which has been so generally feared in cases of fibroid tumours of the uterus." Dr. Sutton, who has a private hospital and belongs to the Tait school of gynecologists, bitterly opposed this method, and publishes a challenge to Dr. McKee, in which he offers to furnish him with three patients suffering from fibroid tumours of the uterus, furnish all the apparatus necessary, and support Dr. McKee and the three patients in his private hospital, and for each tumour removed, give the Doctor 1000 dollars, time limited to one year. Dr. McKee is to be the loser. Dr. McKee accepts the challenge provided all the conditions remain the same, except that the contest takes place in Cincinnati instead of Pittsburgh, not feeling justified in relinquishing his practice for six months or a year for the inducements offered. Dr. McKee cites as on his side many men of prominence as gynecologists.

THE LATEST RESULTS OF THE PASTEURIAN TREATMENT.

At the Epidemiological Society, London, February 13th, 1889, Mr. Victor Horsley attempted to give the failing Pasteurian method a little assistance, this being done by a paper, full of fallacies, upon the exposure of which it is almost useless to waste any more ink. The "too late" theory will hardly now be accepted in view of actual deaths, after two hours elapsing between the bites and the treatment; whilst, if the "too late" plea be accepted, say in the case of Lord Doneraile, then every case over eleven days must also be wiped out from the statistics, whereby they would be very much diminished. The latest deaths reported hardly sustain the panegyrics showered on the method. The following are particulars of three deaths, taken from the *Journal de Médecine de Paris*, February 17th, 1889:

Case I.—A——, of Cambes, Gironde, bitten on the hand, December 25th, by a dog suspected to be rabid. Cauterised five hours after bite. Sent immediately to Paris. Treatment commenced on December 28th. (This comes within the six days, and can hardly have a "too late" excuse.) Treatment continued for *four days*. The patient was sent to her home "*gueri*:" on January 12th began to be ill, then sent to Hospital for Children, dying of rabies of the convulso-paralytic type. Period of incubation, 16 days.

Case II.—X——, æt. 19 years, of Peyres-tortes, Pyrenees, bitten December 8th by a dog suspected to be rabid. *Sent the same day to Paris, where the Pasteurian method was immediately applied.* Treatment continued for the whole month. Patient discharged "cured." On the 5th January the poor fellow began with symptoms of rabies, dying on the 9th January, at Peyres-tortes. Incubation thirty days.

Case III.—Rose M——, æt. three, of Belbeuf, badly bitten, December 13th, by a dog, which had been bitten by a suspected dog. Sent *immediately* to Paris, and treated from December 15th, 1888, to January 5th, 1889. The child died of mixed rabies on the January 9th. Incubation twenty-two days.

The editor says: "These three cases in which the Pasteurian method was immediately applied at the laboratory itself, and with all the perfection introduced into Pasteurian therapeutics during the past year, carry with them a sad lesson. Not only these cases of death, added to the 160 we have already collected, demonstrate that M. Pasteur does not cure rabies, but they confirm the fear we were the first to express in 1887. At that period owing to the numerous deaths which had taken place in individuals who certainly had not rabies when they entered the laboratory, and who succumbed after presenting symptoms of a medullary affection, we said: the first method of treatment was inefficacious; the second method is dangerous. The mortality during 1886 in France, is higher than the mean mortality of twenty preceding years. Three years have passed since our initial protestations. We have now carefully collated all the facts; the mortality in France during three years has not diminished."

If we examine the recent facts, and notably the three cases of death above described, we shall see that the period of incubation has considerably diminished. Whilst the incubation was at a mean two months, now we see it at twenty-two days, so that we might conclude that the introduction of the spinal marrow, made by Pasteur, hastens the evolution of this terrible malady. This is a serious result, and well worthy of reflection. We are rather astonished at the appeals made to the English Government to subscribe to the Pasteur Institute. It is evident that M. Pasteur does not want funds, but he wants the prestige that will accrue to him from the support of the English Government. He could then turn to the crowd of unbelievers in Germany, Austria, Belgium, Holland, America; and say, "Look! at this endorsement from this noble Government of England, and its gratitude because I have treated two hundred patients." This would be a better card in his hand than the one he holds from the Sultan of Turkey or the Emperor of Russia. It is most remarkable that whilst all civilised countries are reducing their mortality from rabies, by simple measures, and without a Pasteur Institute, France, which is employing the same measures and which is the home of Pasteur, enjoys the questionable prerogative of having more dog-bitten patients than any other country, and as high a mortality as it has had any time—taking the mean mortality of the last twenty years. France has her palace of rabies. Is she to become the home of rabies?

New Remedies.

Arecoline.—It is now about three years since a volatile liquid alkaloid called *arekane* was separated by Herr Bombelon from areca nut. In a recent report by Herr Jahns, it is now stated that three alkaloids can be obtained from the same nut. The most important of these is arecoline ($C_8 H_{13} NO_2$), a colourless liquid alkaloid, readily soluble in water, alcohol, ether, and chloroform, and distilling at about 220° C. Its salts are mostly crystalline, readily soluble and hygroscopic. The hydrobromide, however, is not hygroscopic, and is the most stable of the known salts. Arecoline appears to be the special active principle of the drug to which its tænicidal properties are due, and approximates in its chemical composition to pelletierine, the vermifuge principle of the pomegranate, the formula for the latter being $C_8 H_{15} NO$. The second alkaloid discovered by Herr Jahns, arecaine $C_7 H_{11} NO_2 H_{20}$ is crystalline, stable, readily soluble in water and dilute alcohol, but insoluble in ether, chloroform, and benzol, and almost insoluble in absolute alcohol. It seems doubtful if this alkaloid is, strictly speaking, a true alkaloid, since its aqueous solution is neutral in reaction. It, however, appears to combine with acid, forming crystalline compounds, having an acid reaction and soluble in water. It appears to be physiologically inactive. It appears possible that arekane may have been only an impure form of arecoline, since they are both soluble in ether; the salts of the former were, however, only obtained in a varnish-like form, whilst those of the latter were procured in a crystalline state.

Strophanthus.—Recent researches have shown that the strophanthin obtainable from different species of strophanthus are not identical. M. Arnaud has proved that the active principle of *S. glaber*, a native of the Gaboon, is not the same as that of S. Kombe, although curiously enough it appears to be identical with an active principle called oubain, obtained from a plant called by the author Aokanthera ouabaio. Specimens of the crystals of oubain were exhibited at the February meeting of the Pharmaceutical Society in London. The diuretic principle of strophanthus is stated by M. Catillon to be left in the seed after the removal of all the strophanthin, and to consist of an amide, obtained as a calcium compound. It is soluble in water, 70 per cent. alcohol, and gives some alkaloid reactions. It is less soluble in strong alcohol. Its diuretic properties have been tested both upon rabbits and human beings.

Antipyrin seems likely to prove a valuable remedy in more ways than one. Introduced at first as an antipyretic, it is now known to possess powerful anodyne properties over pain of rheumatic origin or neuralgia, a single dose being sometimes sufficient to relieve pain and cause sleep when ordinary remedies have failed. The unpleasant symptoms sometimes arising from its use, such as urticaria, congested mucous membranes, and full and quick pulse, have been found to give way under treatment with small doses of atropine.

β-Napthol mercury has just been introduced under the name of *Hydrargyrum naphtholicum*, as an antisyphilitic remedy. It is in the form of a neutral, yellow, odourless powder containing 30·8 of metallic mercury, and is insoluble in ordinary solvents. It forms a green oily liquid when melted, but if heated more strongly carbonizes, globules of metallic mercury being set free. Mixed with 50 or 100 parts of roasted kieselguhr, or rubbed up with fresh albumen and diluted with water, it is said to promote the healing of wounds in a wonderful manner. It is said to be also very useful in the treatment of typhoid fever, since it has a specific action in killing the typhoid bacillus. For this purpose it is given in doses of 0.05 grain several times daily, according to the weight of the patient. A naphthol-mercury acetate has also been prepared in the form of a pale yellow, odourless and tasteless powder. A third new mercurial compound is thymol-mercury acetate, which is stated to have been used with success as an antisyphilitic. Internally it has been given in the form of a pill, in doses of 0.05 to 0.1 gram. Externally it has been administered in the form of intra-muscular injections, which are stated to seldom produce either smarting or infiltration. It is a white crystalline powder, tasteless and odourless, almost insoluble in water, but soluble in dilute alcohol.

Euonymin.—Attention has lately been directed to the fact that euonymin, as met with in commerce, is a very unsatisfactory preparation, due in great measure to the demand for a *green* euonymin, under the erroneous supposition that it is a better article than brown euonymin. The analysis of several samples obtained from different makers has shown that no sample out of twelve examined contained more than 35 per cent. soluble in rectified spirit; and in four specimens 20 per cent. of barium carbonate were found. No barium carbonate was found in brown euonymin. It appears that in order to supply euonymin in powder, most of the American manufacturers find it necessary to add to the alcoholic extract twice its weight of some absorbent powder. As euonymin is generally prescribed in pills, and there is no special advantage in using the powder, it is obvious that the profession would find it to their advantage to order an alcoholic extract of the bark of euonymus atropurpureus rather than a powder for which no definite formula exists, and which varies in strength according to the quantity and kind of diluent added by each manufacturer.

Embelia ribes was some few months ago examined by Dr. C. J. H. Warden, of Calcutta, who found the active principle to be embelic acid. This substance, however, being insoluble in water, salts of potash ammonia and soda were prepared, and it was found that the ammonia salt was the one most readily obtained in the crystalline form, the acicular crystals having a fiery red hue. It is made by adding excess of ammonia to a strong alcoholic solution of embelic acid, and allowing the liquid to evaporate spontaneously. Experiments made with the ammonium salt show that it is an effective tœnicide in doses of three grains for children, and six grains or more for adults, and that it succeeds in cases in which ordinary tænicide fails. It is moreover tasteless, thus presenting a considerable advantage over male fern. A considerable quantity of the fruit of embelia ribes has recently been sent to this country from India, and the remedy is therefore now practically within reach of the English therapeutist.

Nitrite of amyl.—Some experiments lately made by Dr. Lauder Brunton and Professor Cash with pure nitrite of amyl, prepared in the Research Laboratory of the Pharmaceutical Society, show that the pure preparation is less active than the ordinary nitrite of amyl met with in commerce, and that this is probably due to the fact that the commercial article usually contains a mixture of α-amyl nitrite, β-amyl nitrite, and isobutyl nitrite, the latter being present to the extent of about 10 per cent., also propyl nitrite, the amyl nitrites constituting about 10 to 50 per cent. of the mixture. The pure isobutyl nitrite has been shown by Professor Cash to be more active, or at all events more prompt in its action than a mixture of the α-amyl and β-amyl nitrites, and to be more powerful than the official liquid, which contains all three nitrites. The action of the pure α-amyl nitrite is still under investigation by Professor Cash.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

A New Method of Treatment of Synovial and Sebaceous Cysts, and Superficial Cutaneous Cysts generally. By Dr. H. Barth, of the *Hôpital Broussais* (*L'Union Médicale*, January 15th, 1889).—After one or more punctures, and the injection of Fowler's solution into a lymphadenoma, a certain amount of local reaction is observable, with swelling and increased sensibility in the tumour, and the formation of abscess seems impending, but if the injection be not repeated things will go no further. In the course of a few days the inflammatory appearances subside, the tumour returns to its primitive dimensions, and will undergo a consecutive atrophy and finally disappear altogether. Miniwarder, who has studied the effects of these arsenical injections, explains the result as being the effect of the arsenious acid in causing disintegration of the albuminous elements of the structure—a necrobiosis of the tissues, favouring their absorption. This purely chemical theory appears to M. Barth to be insufficient

to explain the special action of arsenic on the morbid structure, but that a moderate degree of inflammation in the gland favours its atrophy in accordance with the laws of the absorption in general of morbid products. From this datum it was probable that certain non-malignant tumours might be treated in the same way. The first case in which he put this plan into execution was that of a girl, aged twelve years, having a ganglion on the wrist which had resisted all other methods of treatment. The operation occasioned some swelling, which, however, shortly subsided, and the tumour disappeared. In the next instance the patient was a woman, aged thirty years, who had a wen which no local applications affected. One drop of the Fowler's solution was injected, and followed by the same phenonema as the ganglion before-mentioned. A second injection was required in this instance. In fifteen days the wen had wholly disappeared. M. Barth records six others of sebaceous, besides several synovial cysts. In one case the arsenic appeared to have escaped into the adjacent structures, and caused inflammatory swellings, which however subsided after a few days. No inconvenience has been seen to result from the use of arsenic as above indicated, care having been taken as to the nature of the cysts and tumours operated upon. The manual operation is simple, the wound not more than that inflicted for the injection of morphia. The pain does not endure long, and may be notably diminished by the addition of one or two per cent. of cocaine to the Fowler's solution.

Spasm of the Glottis, of Nasal Origin (*L'Union Médicale*, January 15th, 1889).—Dr. Ruault submits the following conclusions:—1. Certain lesions of the mucous membrane of the nasal fossæ may provoke reflex spasm of the glottis, so serious as to demand tracheotomy. 2. These attacks may continue for years, and yield quickly to treatment of the nasal affection on which they have depended. 3. Both sexes present instances, but hysterical females are most frequently subjects thereof. 4.—Infants as well as adults may be attacked by this form of spasm. 5.—Bronchial spasm may occur at the same time. 6.—Affections of the voice are a complication often met with. 7.—Prognosis is favourable where the cause is known. 8.—Diagnosis is obtained by exclusion of other causes, by the history of the case, and by rhinoscopical examination with the help of a sound and the use of cocaine. 9.—The treatment of an attack is, according to its severity, bathing the parts with solution of cocaine, the administration of chloroform, and the operation of tracheotomy if required. 10.—Treatment is to be directed to the affection of the nostrils.

Case of Partial Aneurism of the Left Ventricle of the Heart. By Dr. Nino de Andrade (*L'Union Médicale*, quoted from *O Brazil Medico*, September, 1888).—The patient, an intemperate man, had suffered from marsh fever, presented a case of ascites, without œdema or albuminuria. After the performance of paracentesis the liver was found to be greatly enlarged. The dulness of the right side of the heart was much extended, a systolic *souffle* existed, its maximum being heard over the jugular vein. In the reclining posture the venous distention was "enormous," but disappeared on resuming the upright position. The diagnosis was insufficient tricuspid valve, compression of the diaphragm and vena vava by the liver in the horizontal position. Autopsy: partial false aneurism of the left ventricle, situated in the angle of the intra-ventricular groove. This appeared to be due to myocarditis that had followed upon pericarditis, the thickened pericardial deposit formed the external wall of the aneurism, communication existed with the ventricle by two openings. The venous pulsation and the *souffles* were caused by compression of the auricle by the aneurism.

Progressive Pernicious Anæmia (*L'Union Médicale*, January 22nd, 1889).—The investigations of MM. Planchard, Hanot, and Legris have established the fact of the existence of the disease named PERNICIOUS ANÆMIA, a disease which may be distinguished from those states of the blood in which an autopsy reveals the cause. From the etiology of the disease, cancer, tuberculosis, and intestinal worms must be excluded. The anæmic condition may be secondary to the presence of the last named organisms. Among the effective causes are debilitating agencies, distress, excesses, and pregnancy. This last explains the more frequent occurrence of this condition in women than in men. The disease also occurs frequently after prolonged diarrhœa. The morbid condition affects the entire body; the viscera are discoloured, the liver and digestive organs show most notably their lesions, the mucous membrane of the stomach and intestines is thickened and degenerated; fatty degeneration of the liver is observed in most instances. The most important alteration is observed in the blood; its colour becomes like that of amber, and coagulation takes place tardily, the number and colours of red globules is diminished, their size is somewhat increased. The authors quote Dr. Copeman (*St. Thomas's Hospital Reports*, xvi.) to the effect that the red blood globules are generally small, 4 to 6 μ, and that minute globules are present, 3 μ (1 μ = about $\frac{1}{25000}$ English inch). The formation of crystals of hemoglobine, noted by Dr. Copeman in the blood when a drop is allowed to dry, is also repeated by the authors. Several observers who have noticed the larger size of the blood globules are cited. M. Planchard has collected the results of bacteriological examinations of the blood. Bernheim has observed long jointed bacilli, which however Feltz and Engel have not been able to cultivate or inoculate. Fraakenhauser and Petrone have described small, spheroidal, and moving organisms, of about one tenth the diameter of a blood globule, furnished with processes; with these also other longer and more mobile forms. Petrone had inoculated rabbits with these micro-cocci, and induced general anæmia. No actual results have been obtained with reference to analogy between pernicious anæmia and microbic infectious diseases. The symptoms in this malady are dependent upon the poorness of the blood; they are gradual in their approach; debility is general and progressive. The intellect is not generally impaired, but there may be slight and passing attacks of delirium. Palpitation, with systolic *souffle*, is commonly to be heard. Hæmorrhages are frequently met with. Deranged digestive functions also are very general. Although named *pernicious*, this form of anæmia is not incurable, and remissions occur after long intervals, the course is almost always to death, which may occur suddenly from an intercurrent disease, or take place slowly with gradual failure of all the powers. Of remedies, arsenic appears to be the most reliable medicine.

On the Use of Linen Thread for Ligatures and Sutures. By Dr. Heyder, St. Johanne's Hospital, Bonn (*Centralblatt für Chirurgie*, December 22nd, 1888).—The high price of surgical silk (in Germany ?) has determined Professor Freudelenburg to use hemp or linen thread for sutures and ligatures. The thread is prepared for surgical purposes by steeping it for twelve hours in a one-per-cent. solution of corrosive sublimate.

New Remedies.—*Sulphonal—a New Narcotic* (*Journal de Médicine de Paris*, January 20th, 1889).—Two notices of this substance have appeared in the preceding volume of this journal (pp. 278 and 320). We supplement these by the following abstract. Sulphonal is a hydrocarbon existing in the form of a prismatic crystal, soluble only in 100 parts of cold water; soluble in twenty parts of boiling water, alcohol, ether, benzole, and chloroform. One of the earliest observers, Prof. Kast, of Fribourg, noted that when administered to dogs it produced signs of drunkenness followed by sleep. In man, the dose of a gramme given at bedtime produced sleep in about an hour's time—sleep was light, but dreamless, succeeded on waking by a condition of comfort. Sulphonal is of service in nervous insomnia in doses of from one to two grammes. As the case with all good hypnotics, having produced the desired effect a few times, sleep will follow sometimes merely under the influence of suggestion, without the sulphonal. It has been given with benefit in the neuralgic and rheumatic affections, in delirium tremens, in mania, hypochondriasis, and in acute febrile disorders. In morphiomaniacs it may be given in doses of two grammes as a substitute for morphia. It occasions no disturbance of the heart's action in hypertrophy. This medicine being tasteless, may be given with bread, milk, tea, warm fluids, and alcoholic drinks.

"*La Phénacethydeazine.*"—A new antipyretic recently introduced by M. Dreschfeld. M. Lepine states that he has administered this remedy in cases of locomotor ataxia with advantage in doses of three grammes.

Aërated Milk.—Milk is not used only as an alimentary substance, it is also frequently employed as a medicinal agent; such is the mixture of milk with aërated water in disorders of digestion and affections of the lungs. The carbonic acid of aërated water is said to promote the digestion of the proteic elements of milk. The insipidity of the mixture may be obviated by the direct addition of the carbonic acid to the milk, and sapidity ensured by an addition of about twenty grains of bicarbonate, or chloride of sodium, the addition of which favours also the presevation of the milk. This may be employed pure or skimmed. The aërated milk is an excellent remedy in hoarseness. If the milk be desired sweet small quantities of sugar or saccharin may be added.

The Disinfecting Properties of Lime.—The influence has been examined (1) of lime water upon the bacilli of typhus and cholera; (2) of milk; (3) of powdered quicklime; (4) of fragments of quicklime, upon the bacilli of cholera. The following results are stated: (1) An aqueous solution of lime, 0.0074 to 0.0246 per cent., kills the bacilli of typhus or cholera in an hour. (2) The culture of cholera bacilli in bouillon is completely disinfected by the addition of 0.4 to 0.2 per cent. of caustic lime. (3) This destructive action is most energetically exerted when powdered quicklime, or milk of lime, is used at twenty per cent. Hence quicklime is to be regarded as an active disinfectant.

Diuretic Action of Strophanthus (*Journal de Médicine de Paris*, January 20th, 1889).—At the sitting of the Academy of Medicine,

Paris, January 15th, M. Dujardin-Beaumetz dwelt upon the superiority of strophanthus over that of digitalis in feebleness of the heart's action. Its only inconvenience he pointed out was its tendency to produce diarrhœa if its use be prolonged. Its diuretic action is prompt and rapid. Where there is deficient urinary secretions, its use should be suspended if diuretic action is not induced in twenty-four or forty-eight hours.

The Removal of a Sub-mucous Myoma by Laparotomy. By Dr. H. W. Freund, Strasbourg (*Centralblatt für Gynäkologie*, December 8th, 1888).—The patient, a woman forty-five years of age, had always enjoyed good health, had menstruated at the age of twelve years, regularly every few weeks. Six years since had borne a living child after a lingering labour, but suffered from detained placenta, and for six weeks was confined to her bed by uterine hæmorrhage. Subsequently the catamenia had become more profuse, her strength had diminished so that she could scarcely hold herself erect. On the 8th October she was admitted into hospital. She was then anæmic, and presented evidence of a tumour reaching to the umbilicus, and giving the appearance of pregnancy at six months, which however was excluded by the absence of auscultatory sounds and fœtal movements. Internal examination showed a fœtid yellowish discharge. The mucous membrane of the external organs was of a livid colour. The cervix uteri was firm, and admitted the finger to the internal *os*. In the dilated uterus the lower part of a hard tumour could be felt, inclined towards the right side of the fundus; no pedicle could be discovered. The removal of the tumour was indicated, but its size and connections precluded its removal by the natural passage. Two modes of its removal offered themselves; one the amputation of the entire uterus; the other the removal of its contents. The selection depended upon the diagnosis of the nature of the tumour. The operation of Professor Recklinghausen was determined upon. An incision was made into the *linea alba*, three fingers' breadth above the pubis. The abdominal walls were fat, the muscles well developed, peritoneum not adherent, no aseiles. The uterus rose in the incision, and had the size and appearance of six months' pregnancy; the appendages were normal. A tumour was met with in the interior cavity, and removed by the hand through the incision in its anterior wall, very little force being required for its detachment from the fundus on which it was placed. It then appeared that a second intra-uterine tumour was present at the posterior and left side of the fundus, it was readily removed by manual effort, and found to be another fibroma. The emptied uterus was much enlarged, and possessed a markedly thick muscular substance. The mucous membrane of the uterus was much thickened, and thrown into folds. The sublimate solution and iodoform were used in the performance of the operation. The healing of the wound took place without anything untoward. The weight of the tumours was 1520 g. (equal to 47 oz. 4 dr. English), they consisted of a fibrous, and in some places spongy tissue, in some parts hard nodules, but for the most part consisted of a fine porous cyst-like texture, containing a serous fluid.

On the Salutary Action of Perfumes (*Journal de Médicine de Paris*, January 20th, 1889).—M. Ungerer considers that perfumes and flowers exert a salutary influence over the system, and constitute a therapeutic agency of the first order. Residence in a perfumed atmosphere, he states, protects from pulmonary affections, and arrests the development of phthisis. Seven individuals, he alleges, submitted to this odoriferous cure had rapidly recovered their health. In support of his opinion the author states that in the city of La Grasse, the garden of Europe, phthisis is rare, an immunity owing to the odorous vapours exhaled from the numerous distilleries.

A New Method of Mixed Narcosis (*Centralblatt fur Chirurgie*, No. 49, December 8th, 1888).—M. Obalinski recommends the simultaneous local use of cocaine with the inhalation of chloroform. The quantity of chloroform required is much less, and sickness occurs much less frequently. Such local anæsthesia with half chloroformization is more certain than chloroform alone. The reporter, however (in *Centralblatt*), considers that this statement is not sufficiently borne out by results.

Report upon Thirty-seven Ovariotomies (*Centralblatt für Gynäkologie*, No. 1, 1889).—Dr. Dionys von Szabó, of the University, Budapesth, reports the particulars of thirty-seven cases in which he has performed ovariotomy. Of the thirty-seven operations four only passed through the period of recovery without elevation of temperature. In four slight elevation took place for a day or two after the operation; in nine there was some increase during the first four days; the subsequent course was free from febrile symptoms. In fourteen cases there occurred fever, followed by suppuration at the sutures. Two patients died of septic poisoning.

Total Extirpation of the Uterus (*Centralblatt für Gynäkologie*, January 5th, 1889).—At a meeting of the Association of Accoucheurs, of Berlin, November 23rd, 1888, Herr Keller exhibited an uterus affected with carcinoma, which he had removed from a patient seventy-five years of age. Thirty-eight years previously this patient had borne a child, and had ceased to menstruate twenty-five years since. Hæmorrhage had occurred at irregular intervals since last march. The uterus on examination had been found retroflexed and fixed, but the appendages were free. In August an exploratory curette brought away a portion of what proved, on microscopical examinination, to be an adeno-carcinomatous growth. In September the total extirpation of the uterus was effected by Dr. Winter, with some difficulty, on account of the narrowing of the vagina. The uterus was placed in alcohol to harden. On being opened the cavity appeared large relatively to the thickness of its walls. In the posterior wall, which was thickened, a myoma of about the size of a cherry was imbedded in the muscular substance. A tumour having a flocculent surface was found on the anterior wall; this tumour was soft and of a reddish grey colour, and passed gradually into the substance of the uterine walls. The cavity of the uterus was otherwise filled with coagula.

On the Treatment of Uterine Fibromata by Intra-uterine Electrolysis. By M. Deletang (*L'Union Médicale*, November 29th, 1888).—The immediate effects of electrolysis consist in (*a*) contraction of the uterus and its tumous; (*b*) congestion of the adjacent organs, continuing for several hours, and attended with colic; (*c*) sometimes a rapid subsidence of pre-existing hæmorrhages. The consecutive effects are: 1. Slight hæmorrhage. 2. Pain, with functional disturbance, quickly passing off. These phenomena have no relation to the tumour, but belong rather to the inflammatory zone surrounding it. 3. The mass diminishes. The morbid phenomena disappear, and the general condition improves. There may be a momentary aggravation of symptoms at the commencement of the treatment, depending upon congestion of the inflammatory zone.

II.—NOTES FROM FRENCH JOURNALS.

By H. R. HATHERLY, M.R.C.S.

Aneurism of the Subclavian (*Journal de Médicine*).—Dr. Saboia has laid before the Society of Surgery notes of a case of aneurism of the subclavian treated successfully by electro puncture. The treatment was continued fifty-five days.

Catholic Faculty of Medicine (*Gazette Hebdomadairè des Sciences Médicales*).—It is seriously proposed to establish a Catholic Faculty of Medicine at Lyons; a subscription list has been opened, and the first list of sums promised amounts to 400,000 francs.

Poisoning by Acetanilide (*Journal de Médicine de Paris*).—A case has been reported of death from an over-dose of antifebrin. A physician had ordered a dose of a quarter of a gramme to be given night and morning to a child. The father, however, who was over anxious, repeated the dose every two hours on his own responsibility. In the evening the child was found to be cyanosed, and suffering from collapse, the pulse being very rapid and feeble. The child died notwithstanding all efforts to neutralise, the effects of the over-dose.

Heavy sentence on Medical Men (*L'Union Médicale*).—Two medical men at Liege, who had been called upon to make a *post-mortem* examination on a patient who died from infectious metro-peritonitis under suspicious circumstances, have received an unusually severe sentence for forming conclusions which the autopsy did not warrant. The autopsy appears to have been made very carefully, every organ being minutely examined, and the evidence of a recent miscarriage was placed beyond doubt, but the medical men, Messrs. Grenson and Lenger, unfortunately for themselves, were of opinion that abortion had been caused by criminal practices. The summary of their official report is as follows:—

1. Marie Constant, the divorced wife of Dumont, has died from general, acute, purulent, and septic peritonitis, resulting from an extension of inflammation of the uterus and its appendages.

2. *This inflammation of the uterus and its appendages is the consequence of a mechanical irritation, which has caused an unnatural abortion about the sixth week of pregnancy.*

Accepting the general conclusions of the medical witnesses as to the fact of miscarriage, and even admitting that placental debris were found after six weeks pregnancy; accepting also the fact that death was due to puerperal peritonitis, the question arises: what were the facts on which they relied as justifying the addendum that the abortion was artificial, and the consequence of mechanical irritation? One of the medical witnesses affirmed before the correctional tribunal, "that they could not have formed so precise an opinion from the *post-mortem* alone, but they also had possessed the confidence of the woman." *L'Union Médicale* considers that such a statement in the mouth

of a witness, whose services are called in for a purely scientific object, is beyond comment. The result of the conclusions arrived at by Drs. Lenger and Grenson (based on private information in addition to strictly medical facts), has been a sentence of: four years imprisonment, a fine of a thousand francs, and forfeiture for five years of all civil and political rights (!)

A Medical Privilege (*Journal de Médicine de Paris*).—The right of a medical man to prior claim for his fees, although rent may be due to his patient's landlord, has not infrequently given rise to disputes in France. The courts of Rouen, Poitiers, and the Seine have decided that the debt due to a medical man for professional services must take precedence of any claim the landlord may have for rent: "It is an imperative motive of humanity which has guided the legislator in not depriving the dying of those cares which are absolutely necessary."

Syphilis in Paris (*Journal de Médicine de Paris*).—Dr. L. de Pileur has made a minute study of the statistics of syphilis in Paris, as it affects the mortality of mothers and infants, and the mathematical conclusions derived from his researches are as follows:

1. *Out of every one hundred pregnant women, fourteen will be syphilitic.*

2. *Out of every one hundred born of syphilitic mothers, including premature births and still births, seven at the most will survive a few months of their existence.*

Therefore it will be seen out of 64,657 births, or products of conception which took place annually in the town of Paris, 9,051 will be born of syphilitic mothers. Of these 8,418 will be still-born, or live only a few months after birth; 633 only will survive the first few months of extra-uterine life.

3. Out of one hundred children born in Paris, thirteen will die in consequence of syphilis in the mother, independently of all other causes of mortality.

Vaccination in Schools (*L'Union Médicale*).—An important regulation has recently been issued by the Minister of Public Instruction on the subject of vaccination. Henceforth every child who has attained the age of ten, must before being admitted or maintained in a primary school, be re-vaccinated by the medical officer attached to the school, or appointed by the school administration. In addition every candidate for a normal primary school must be provided with a certificate of vaccination and of re-vaccination.

Treatment of Exophthalmic Gôitre by Cultivated Hemp (*L'Union Médicale*).—The physiological action of cultivated hemp is similar to that of Indian hemp, but cerebral phenomena are either not produced or are much diminished. It requires double the dose to produce the same effect as Indian hemp. The most active preparations are the resin of hemp, the tincture, and the dried leaves in lozenges, tinctures, and fumigations. In the last place we have the pharmaceutical extract of the fresh herb, and the aqueous extracts. Dr. Valieri cites three cases of exophthalmic gôitre in which considerable improvements was obtained whilst exhibiting this remedy.

Treatment of Cholera (*L'Union Médicale*).—The number of new remedies for cholera, which have been brought under the notice of the Academy of Medicine amounts to four. M. Gamaleia recommends vaccination; M. Duboué (of Pau) intra-venous injections of water; M. Gibier advises bichloride of mercury; and M. Löwenthal (of Lausanne) salol. Such a variety of treatment does not appear to penetrate the obscurity which still surrounds the therapeutics of cholera.

Treatment of Acne (*Journal de Médicine de Paris*).—Lassar recommends the following treatment of acne: Apply an ointment of naphthol (one part to ten of excipient), and in half an hour or an hour's time wipe it off with tow, and wash the part affected, using soap. The following day a slight irritation with desquamation of the skin will be noticed; the treatment must be continued daily for a week or sometimes a fortnight, when desquamation will be complete. No scar is produced. If the irritation is too severe it can be relieved by an application of oil or of some emollient ointment. In obstinate cases ten per cent of camphor may be added to the naphthol ointment, but in such cases the ointment should be applied for half an hour. Another remedy which has yielded equally good results, is an ointment composed of resorcin, two and half parts; oxide of zinc and starch, of each five parts; vaseline, twelve and half parts. The ointment must be applied to the part affected during a day and a night, and removed by oil.

Chronicles of Hydrophobia (*Journal de Médicine de Paris*).—*La Semaine Médicale*, formerly an insane Pasteurite, at present never allows an opportunity to pass of having a sly hit at "the great man," since Messrs. Grancher and his colleagues have started the *Bulletin Medical*, which is a rival publication. The following paragraph is from the *Semaine*: "M. Grancher having announced, in the speech which he made at the inauguration of the Pasteur Institute, that there were at the present time, upwards of twenty anti-rabic institutions scattered all over the whole world, assigns one to Vienna."

The *Weiner Medicinische Presse* replies to this statement by the following note: "The fact stated by M. Grancher is evidently erroneous. M. Ullmann, the only doctor in Vienna who has, so far as we know, practised anti-rabic inoculations on man, has been obliged to discontinue them, the government having refused to pay the subvention which was absolutely necessary. It is to be hoped that M. Grancher is better informed with regard to the remaining institutions."

To this note the *Bulletin Medical* retorts by a letter from the celebrated Ullmann: "Since the Congress of Hygiene (September, 1887) until the present time I have treated thirty-one persons, all of whom are well." Let us admit the fact: Ullman has inoculated thirty-one persons, bitten or not, mad or not, it matters but little; but how are we to explain that the number of cases of hydrophobia is thirty-one in fifteen months at Vienna; whilst M. Pasteur discovers three or four thousand cases every year in France alone. Decidedly hydrophobia is a very obscure disease! Let us end our chronicle by quoting the vote of the medical hygienists assembled at Brescia, who declared "that the Pasteur method was either useless or dangerous." That has been our opinion for a long time past.

Prohibition of Public Manifestations of Hypnotism (*Journal de Médicine de Paris*).—In Belgium on the proposition of M. Masoin, public exhibitions of hypnotism have been prohibited. We hope that the same course will be adopted in France. Thus spoke M. Gluge at the Academy of Medicine of Brussels: "I have been an attentive spectator of the diverse manifestations, analagous to hypotism, which have taken place during half a century; I noted the alleged action of remedies at a distance, which were believed in until a short time since, and which were already discussed fifty years ago by the magnetisers. All this has fallen into profound oblivion, which is also well deserved. The hypnotism of the present day will vanish in like manner, without leaving the least trace either in physiology or therapeutics."

Salicylate of Mercury (*L'Union Médicale*).—Amongst new remedies may be mentioned the salicylate of mercury. This salt was first studied by Lejoux and Grandval, and was first prepared in Brazil, by Messrs. Veiga and Delgado in 1886, and has been much used by the physicians of the Rio. Dr. A. Duprat has laid before the Society of Biology, an essay on its physiological action, and Dr. Silva Aranjo has devoted much time to its study, and many other authorities may be cited. Salicylate of mercury forms a white inodorous amorphous powder, which contains 50 per cent. of active ingredient. It is incompatible with mineral salts. It may be given in pills containing twenty-five milligrammes three times a day. It is well tolerated by the stomach, and leads to no gastro-intestinal troubles so commonly caused by other preparations. Hypodermic injections have not been much used. Moura-Brazil and Neves da Rocha give the following formula: Salicylate of mercury, five to ten milligrammes; distilled water, ten grammes. Patients has received from six to sixteen injections at intervals of from two to three days. Eight to ten injections are generally required. There is very slight local action, and no abscesses or indications of general poisoning have been noticed. Applied externally salicylate of mercury stimulates enormously the healing of abrasions of mucous tracts, and cutaneous ulcerations. It causes the reabsorption of non-ulcerating syphilomata. Szadek mixes the salicylate with subnitrate of bismuth, and makes an ointment. It has also been used successfully in the treatment of parasitic skin diseases, in urethral injections for blenorrhagia, and as a collyrium in catarrhal and granular conjunctivitis.

III.—NOTES FROM RUSSIAN, POLISH, AND SWISS JOURNALS.

By Valerius Idelson, M.D., Berne.

On the Therapeutic Use of Antifebrin.—In the Polish weekly *Gazeta Lekarska*, No. 48, 1888, Dr. Wroczynski (pron. "Vrotchinskee") says that having employed antifebrin as an antipyretic in a number of cases of croupous pneumonia, pulmonary phthisis, small-pox, scarlatina, and enteric fever, he has arrived at the following conclusions:—(1) In pneumonia, antifebrin proves to act apparently, not only as an antipyretic, but even as a "specific" remedy, since it very markedly mitigates the inflammatory process, and prevents any intense infiltration. It is contra-indicated, however, in pulmonary inflammation occurring in elderly and exhausted people. (2) In phthisis, the drug is of no use whatever, though it is tolerated by patients fairly well. (3) In typhoid fever, scarlatina, and small-pox, any beneficial effects which might occasionally arise from an antipyretic action of antifebrin, are annihilated and outbalanced by harm resulting from a depressing and weakening influence of the drug. In fact, the course of enteric fever distinctly becomes more protracted and aggravated.

Acetate of Lead in Chapped Nipples and Mastitis.—In the Moscow weekly *Novosti Terapii*, No. 12, 1888, page 455, Dr. A. Nesvitzky highly recommends the treatment of fissures and erosions of the nipple in suckling women, by means of daily dressing with the following salve :—

℞ Plumbi acetici .....gr. ix.
Solve in aq. distill. ..... ʒ ss.
Deinde adde cera flavæ ..... ʒ ij. ss.
Vaselini flavi ..... ʒ j.

M.D.S.—To spread a layer as thick as a table knife's back on a piece of soft linen, and to apply to the parts. A considerable amelioration of all subjective symptoms occurs within twenty-four hours, the lesions healing fairly rapidly. The same dressing is employed by Dr. Nesvitzky as successfully in cases of painful indurations of the mammary gland, occurring during the lactation period. The plaster should cover not only the affected part, but also an adjacent healthy zone. The results obtained by the author in the said affections are so uniformly successful, that he has long ago given up all other means, such as various lotions, paintings, cauterisation with nitrate of silver, etc.

Jequirity in Ophthalmic Practice.—In the Kïev bi-monthly *Vestnik Oftalmologii*, Nos. 4 and 5, 1888, page 339, Dr. Serghei N. Lojetchnikoff, house surgeon to the Ophthalmic Hospital, Moscow, publishes an able and very instructive account on his extensive experience in regard to the use of jequirity in ophthalmic practice. The main points may be briefly given as follows :—1. Jequirity is one of the best remedies for trachoma and trachomatous pannus, since, when employed in suitable cases, and in a rational way, the drug invariably shortens and ameliorates the morbid process (especially on the cornea), and prepares a favourable ground for a further treatment of the lesions by other means (best of all, by a from eight to sixteen per cent. solution of nitrate of silver). 2. The suitable cases first alluded to are protracted and neglected forms of a genuine trachoma, free from such complications as trichiasis (which should be removed before the jequirity treatment), or acute and subacute blenorrhœal phenomena. Folliculosis and follicular catarrh have nothing in common with trachoma, and, at all events, are not fit for the treatment. 3. The safest and most effective mode of the treatment is said to be this : the drug is to be used in the shape of a five per cent. infusion of powdered jequirity seeds, prepared invariably *ex tempore* by a *cold* maceration of six hours' duration, with a decanthation (without filtration). The eyelids having been everted, and the eyeball carefully protected, the conjunctiva is painted with the infusion, which is allowed to remain in contact with the membrane for half a minute, and then is removed either by irrigation, or by wiping with a piece of dry hygroscopic cotton wool. As a rule, the reaction sets in a few hours, and reaches its maximum in forty-eight hours. Sometimes, however, it develops by far more slowly, or proves to be absent altogether. In the latter case the painting should be repeated in about three days after the first application. In such cases where the reaction is obtained, a second painting should be resorted to only after all inflammatory phenomena have disappeared. A too frequent application of the infusion may give rise to ulcers and sloughing of the cornea, and even to a complete loss of the patient's eyes (as has actually happened in Knapp's and Jacobsohn's cases). 4. Jequirity causes a cicatrical degeneration of a trachomatous conjunctiva, which, while shortening and improving the morbid process, puts an end to the cicatricial degeneration determined by the disease itself. 5. As to the jequirity treatment of corneal opacities (corneal sclerosis caused by parenchymatous keratitis), once highly eulogised by De Wecker, it must be discarded altogether, since it fails to effect cure, but instead, gives rise to a most marked cicatricial degeneration of a previously healthy conjunctiva, obstinate conjunctival catarrh, and even to dacryocystitis. The latter, however, may sometimes complicate *ophthalmia jequiritica* even on the treatment of trachoma, as Drs. Lojetchnikoff, A. A. Basanin, Vossius, and Simi have happened to observe more than once.

Cocaine in Surgical Practice.—In the Geneva monthly *Revue Médicale de la Suisse Romande*, January, 1889, p. 44, Dr. F. Buscarlet, house surgeon to Dr. Reclus's wards, L'Hôpital Tenon, Paris, details the results obtained from the use of hydrochlorate of cocaine as a local anæsthetic in 200 cases of various operations. The drug was invariably employed in the shape of a five per cent. solution which was injected by means of a Pravaz's syringe into the subcutaneous cellular tissue along the line of the incision, the dose in individual cases varying from one to two syringefuls (from five to ten centigrammes of the alkaloid), but occasionally amounting to three or four (fifteen or twenty centigrammes). A complete local anæsthesia was established usually in three to seven minutes, to last for about half an hour. The procedure never gave rise to any alarming accessory effects. In only one patient, æt. sixty-five, with vaginal hydrocele, in whom, after the withdrawal of 250 grammes of the fluid, the cocaine solution had been injected into the sac, the injection was followed, in fifteen minutes, by fainting, accompanied by a sensation of suffocation, coldness of the limbs, cold perspiration and agonising pain about the corresponding groin. The symptoms, however, disappeared after a short while. In a few other cases referring to circumcision, or to ablation of tubercular ganglia, there were observed attacks of suffocation with constriction of the throat, lasting for a few minutes. In all those cases a bad specimen of cocaine was used, which did not bring any anæsthesia. Not a single accident could be registered when a good preparation of the alkaloid was employed. The treatment adopted in the cases mentioned above consisted in hot bottles, subcutaneous injection of ether, and internal administration of half or one gramme of caffeine. On the whole, Dr. Buscarlet comes to the conclusion that cocainisation, when practised with due precautions in regard to the dosage and quality of the drug, represents an as safe as useful procedure, considerably simplifying many surgical operations. It was most successfully resorted to in the following cases : 1. *Incision into purulent gatherings*, including cervical phlegmons, axillary and perianal abscesses, acute suppurative lymphadenitis, etc., where cocaine not only does make the incision quite painless, but also, in virtue of its pronounced hæmostatic actions diminishes bleeding, and allows to operate at leisure. 2. *Incision into, and scraping out, cold abscesses and caseous ganglia.* 3. *Incision into hæmatomata.* 4. *Extirpation of sebaceous cysts, lipomata, fibromata, and hygromata* of a moderate size, in absence of extensive adhesion, involving prolonged dissection. 5. *Circumcision for phimosis*, which is converted by cocaine into a both painless and bloodless operation. 6. *Thermocauterisation of anatomic tubercles.* 7. *Amputations and exarticulations of fingers and toes*, resection of the head of the first metacarpal bone, *curettage* of carious tarsal bone, etc. 8. *Excision of anal fistules*, with subsequent suturing the wound. 9. *Castration* for tuberculosis of the testicle. 10. *Internal urethrotomy.* And 11. *Tapping aud injections of iodine* for vaginal hydrocele.

On Rudimentary Croupous Pneumonia in Children.—Dr. N. Urdariano has published an interesting monograph on the above subject (*Geneva Inaugural Dissertation*, "De la pneumonie franche rudimentaire chez les enfants," 1888), based on the study of eighteen cases from Professor D'Espine's clinic. According to the author's definition, the "rudimentary pneumonia" represents a "croupous pneumonia, usually of a short duration, in which all signs of pulmonary infiltration are reduced to their simplest expression, while all thoracic functional symptoms are either absent altogether, or pronounced so slightly that the clinical aspect assumed by the affection resembles that of an essential fever, but not that of a pulmonary disease." The variety is said to be by no means identical with the so-called "abortive pneumonia," since the former is not necessarily of a short duration, and may occasionally last for eight or nine days (as in a case published by Professor D'Espine). An "abortive pneumonia" is a most frequent variety of the rudimentary one, lasting not longer than three days. The general propositions laid down by Dr. Urdariano are these : 1. Rudimentary pneumonia is a disease which frequently occurs in children. 2. It is caused by Fraenkel's pneumococcus (since the author has been able to detect the microbe in the sputa from two patients of the kind). 3. The affection is characterised (*a*) by a high and usually sudden rise of the temperature ; (*b*) by a commonly short duration of fever ; and (*c*) by a rapid recovery, which is often accompanied by a subnormal fall of the temperature (*hypothermie*). 4. It is differentiated from the classical form (*a*) by a slight and limited infiltration of the lung ; (*b*) by mild functional symptoms, as well as (*c*) by slight physical signs. 5. The predomination of febrile phenomena, and sometimes the presence of nervous complications may lead to considerable difficulties in recognising the true nature of the case, and in differentiating the affection from other diseases.

On Acute Infectious Osteo-myelitis.—At the third General Meeting of Russian Practitioners of St. Petersburg, Professor Alexander A. Bobroft, of Moscow, has read a paper (*Vratch*, 1889, No. 2, p. 50) on "Acute Infectious Osteo-myelitis," in which he puts forward the following corollaries :—1. The disease is apt to occur mainly in adolescents. [The author has met with ten cases of osteo-myelitis, of which nine refer to the subjects of from twelve to nineteen years of age, and only one to a woman of twenty-six.] 3. It attacks usually epiphyses of long bones –namely, the lower one in the femur, and the upper in the humerus and tibia. 3. The pathogenic agent is constituted by the *Staphyloccus pyogenes aureus* which penetrates into the organism, either through some lesion of the integuments (abscess, etc.), or through diseased lungs. 4. The penetration of the microbes alone, however, is not yet sufficient to give rise to osteo-myelitis. The latter can arise only when there are simultaneously present some favourable local conditions, such as traumatic lesions (which were found in six out of ten

cases of Dr. Bobroff). 5. The disease imperatively demands an energetical and an as early as possible surgical interference in the shape of trephining and scraping out the medullary cavity. 6. The operation by itself is harmless. The author has performed it in six of his cases, with one death (depending seemingly upon an incomplete scraping out of the medullary cavity). Of the remaining four cases of his, one died without operation; in three, the treatment was limited to a simple incision into the abscess; two of them died, one recovered.

The Spirit of the Societies.

Royal Medical and Chirurgical Society (Sir Edward Sieveking, M.D., president). **Back-knee, Knock-knee, Bow-knee, and other Deformities resulting from Deficiency of Growth at the Epiphysical Lines.**—Professor Humphry contributed a case and specimen of what he called "back-knee," in which the deformity was seen to result from a sharp bend backward near the upper end of the tibia, due, as it appeared, to a deficiency in growth at the fore-part of the epiphysical line. Knock-knee, it was stated, depended in most cases, not as commonly said, upon over-growths of the internal condyle of the femur—over-growth in a bone, or part of a bone, being a rare occurrence—but upon deficiency of growth of the outer or condyloid part of the femur at the epiphysical line. A specimen was shown. The deformity was in some cases exaggerated by rickety flexure in the femur or tibia, or both, and might be entirely due to such flexure. Bow-knee might be also due to similar flexures in an opposite direction, but was often dependent, partly or wholly, upon deficient growth at the inner part of the epiphysical line of the tibia or of the femur.—Mr. Lockwood brought forward a specimen he had obtained in a dissecting-room from a man, æt. forty-six, in which the condyles of the femur were unequal. It was hard to say whether the external was too large or the internal too small; the former was the more probable, though there was no trustworthy normal size to guide them.—Mr. W. Adams said that the paper of Professor Humphry's formed another example of the great value of his suggestions, in which he thought they would all agree, though it was possible they might interpret his facts differently. Professor Humphry has spoken of all these specimens as rachitic, and had assumed in all of them a weak epiphysical line.—A good discussion took place on the paper, which was joined in by Mr. E. Owen, Mr. Pye, Mr. Willet, Mr. Noble Smith, and Mr. C. B. Keetley.

* * * *

Northumberland and Durham Medical Society (James Murphy, M.D., president). **Progressive Muscular Atrophy.**—Professor Philipson exhibited a seaman, æt. sixty-four, who had been shipwrecked four times, a circumstance which probably played a part in the causation of his illness. Twenty months before he had weakness in the left arm; he was now unable to raise it, and the right arm was now similarly affected. The deltoids, triceps, and interossei, etc., all exhibited fibrillary movement. The diagnosis was based upon the increasing atrophy, paresis, and fibrillation.

External Urethrotomy.—Mr. Williamson showed a man upon whom he had operated for gonorrhœal stricture, followed by retention of urine, œdema, sloughing of the penis, and perineal abscess. The patient had made a good recovery, being now able to hold his urine for five hours.

Rupture of the Bladder.—Mr. Rutherford Morison showed a bladder which he had removed from a man, æt. twenty-five, who had suffered from gonorrhœa followed by retention of urine. On the second day of retention the patient felt something give way in his abdomen, had pain, and vomited. He was admitted into the infirmary in a state of collapse. The abdomen was opened, and in the upper and posterior part of the bladder a hole, the size of a split pea, was found; this was stitched. The patient died on the fourth day from adhesive peritonitis, evidently due to irritation from the urine which had escaped into the abdominal cavity prior to the operation.

Hysterectomy during Labour.—The President read a paper on the treatment of labour complicated with malignant disease of the cervix.—After discussing the question whether cancer favoured or prohibited the occurrence of pregnancy, and declaring himself in favour of the latter view, Dr. Murphy dealt with the question of treatment in cases where (1) the cervix only was affected, and (2) where the surrounding tissues were also involved. He had removed the uterus from a woman, æt. thirty-three, who had been four days in labour. She died from exhaustion the next day. The specimen was shown.

Clinical Society of London (Christopher Heath, F.R.C.S. president). **Nerve Grafting.**—Mr. Mayo Robson (Leeds) showed a little girl, æt. fourteen years of age, on whom he had successfully grafted two inches and a half of the posterior tibral nerve into a corresponding gap in the median nerve in the forearm. He also showed the tumour which had involved the median nerve, and had necessitated its removal above, and below, to a cord which appeared to be inseparably blended with it. The attachments had to be cut through. A microscopic examination showed that the cord was composed of nerve tissue, and that the patient, on coming round from the anæsthetic, the parts in the hand supplied by the median were found to be devoid of sensation. Mr. Robson had made arrangements to graft the sciatic nerve of a rabbit into the gap of the median nerve, but fortunately Mr. Ward kindly allowed him to arrange his operations at the same time that he was amputating a thigh, and to utilise the posterior tibial nerve, which was taken straight from the amputated leg into the prepared forearm, the transfer from one theatre to another being made in warm carbolic solutions. Two inches and a half of nerve were used, the ends being attached to the proximal and distal portions to the median with a fine catgut suture, without the slightest tension, either on the stitches or on the nerve. The wound was well washed out with perchloride of mercury lotion and carefully sutured. Healing occurred by the first intention. The grafting was performed forty-eight hours after the tumour had been removed; thirty-six hours after the nerve had been grafted, the sensation returned in the parts supplied by the median, so that the touch of a pencil could be localised. Day by day the sensation returned, and at the end of five weeks the slightest touch could be localised.

* * * *

British Gynæcological Society (Dr. Macan, president). **A Broad Ligament Cyst.**—Dr. Edis showed this specimen, which he said was of interest, as it proved the difficulty of diagnosis in some cases. The patient was a single woman, æt. twenty-seven, who said that the catamenia had been regular, though somewhat scanty, and the last period had ceased about ten days before admission. Four months before she had noticed a small hard lump in the middle of the abdomen, which remained the same size for two months and then suddenly increased in size and moved towards the right side. She was seen in consultation by several medical men, and it was thought generally that it was a fibro-cystic tumour of the uterus. *Per vaginam* the cervix was small and pushed back into the hollow of the sacrum. The uterine sound passed about an inch and a half into the uterine cavity. The tumour extended about two inches above the umbilicus, and was about the size of a small child's head. There was an indistinct feeling of fluctuation. She was admitted into the hospital for women and examined very carefully. There was no symptom of pregnancy. As it had undergone development during the preceding month it was decided to open the abdomen and see what it was. When exposed the tumour looked like a fibro-cystic tumour of the uterus. He managed to drag the tumour out, and then made a puncture, letting out a lot of greenish-yellow grumous material. The base of the tumour was embodied in the broad ligament, and attached to the right of the uterus five or six inches long. There was nothing to make a pedicle of, and having divided away as much of the adherents as he could, removed it in the ordinary way.—Dr. Bantock said he did not clearly understand how Dr. Edis treated the pedicle. He never saw a broad ligament cyst that could be treated in the manner described.—Dr. Edis said, in reply, he had listened with the stethoscope, and examined the tumour very carefully by pressure. As regarded the pedicle, he said there was no distinct pedicle, but it seemed as if it were a layer from the uterine muscular tissue. He had thought it more prudent to perforate and divide in separate operations.—The President (Dr. Macan) then delivered his inaugural address, in the course of which he said he appreciated the honour they had done him in making him president: it was also an intimation that they appreciated the efforts that had been made to render Dublin a centre for obstetrical teaching.

* * * *

Royal Medical and Chirurgical Society. **Actinomycosis Hominis.**—A demonstration was given to the members of the Royal Medical and Chirurgical Society, when the subject of the actinomycosis hominis was introduced by Dr. D. Powell and Messrs. Godlee and H. Taylor. The case on which the paper was founded was that of a boy, æt. nine, whose family history was tuberculous, and who had been ill for four months with obscure symptoms of hectic, slight cough, and swelling on the right side of the chest. Over the lower two-thirds of the chest on this side complete dulness existed; the heart was displaced, and a basic bruit could be distinguished. There was no empyema, but on opening one of the fluctuating painful swellings there escaped a mass of degenerated tissue densely packed with the ray fungus. Numerous specimens,

stained and unstained, were shown, and it was shown that the two varieties hitherto supposed to be distinct were really one and the same. The clinical history of the disease was described, and its pathology in men and animals discussed, and also the position of the fungus amongst the organisms producing parasitic affections.—Dr. JOHN HARLEY was much impressed with the importance of the demonstration given to the Society, and especially with the evidence which showed how readily the growth be recognised even in unprepared specimens. He had brought forward a case some time previously which agreed in all essentials with Dr. Powell's except that the presence of the fungus could not be positively affirmed. He suggested that the growth might possibly be an effect rather than a cause, the germ being secondary to tissue disease; and he adduced examples from the vegetable kingdom in support of such a theory.—Mr. EVE narrated the case of a stableman, æt. sixty, who came under treatment for a hepatic swelling, from which much soft granulation tissue was evacuated. Ascites subsequently caused death, and at the *post-mortem* examination actinomycosis of the liver was found, though inoculation experiments with the tissue were successful.—Dr. T. D. ACLAND referred to the difficulty experienced in staining the club formations of the fungus when it occurs in man, notwithstanding the case with which any method of staining succeeded in cattle. Dr. MARKHAM SKERRITT described a case under his care in 1886, the patient being a house decorator, æt. twenty-eight, with a tuberculous family history. The disease originated in the lung and spread by migration to the liver. Dr. Skerritt considered the disease identical with that infecting cattle, and that it was much more common than was generally supposed.—Sir DYCE DUCKWORTH mentioned a case of actinomycosis of the skin, which Mr. Eve said was shown, by its subsequent history, to have been lymphosarcoma. Dr. POWELL and Mr. GODLEE having replied, Prof. Crookshank said he thought that staining of Dr. Harley's specimens in the fresh state would have revealed the clubs. In Dr. Skerritt's case they were easily found on careful re-examination. They did not stain well in man, though when inoculated in the calf they came out very clearly.—Dr. CROOKSHANK gave a full demonstration of the microscopical character of the fungus.

* * * *

MEDICAL SOCIETY OF LONDON. **Epilepsy with Intellectual Aura.**—At a meeting of the above Society, Dr. Edmund Owen in the chair, in the absence of Sir William MacCormac, Dr. HUGHLINGS JACKSON and Dr. BEEVOR read the notes of a curious and rare case of epilepsy with "intellectual" aura, which was associated with a tumour in the temporo-sphenoidal lobe of the brain. The patient was a cook, æt fifty-three, and had suffered from fits for thirteen months previously. She was admitted into the Hospital for Epilepsy and Paralysis on November 5th, and remained there until her death on the 31st December. The fits usually began with tremors in the right hand and arm, which were weaker than their fellows on the opposite side. She then used to see a "little black woman always busily engaged in the kitchen," a phenomenon known as the intellectual aura, and experienced a horribly nauseous smell, and then her eyes would become fixed for some minutes, but she did not lose consciousness, although she often passed her urine during the attacks. She suffered very little from headache, but gradually lapsed into a condition of dementia. Shortly before her death she developed double optic neuritis. This is the first case on record in which this perception of a smell has been traced on the post-mortem to disease of the temporo-sphenoidal lobe. The results of clinical observation in this case coincide with those experimentally obtained by Dr. Ferrier.—Dr. JACKSON pointed out that although there was a subjective derangement of the sense of swell, there was no loss of that sense; a fact which was nevertheless of great importance from a diagnostic point of view.—Dr. BEEVOR gave the details of the autopsy when a tumour the size of a small orange was found imbedded in the white matter of that lobe behind the level of the uncinate convolution.

Dr. FERRIER alluded to the peculiarly interesting nature of the case, and its rarity. In the one or two cases of epilepsy with olfactory aura in which a post-mortem examination had been obtained, the results had favoured the supposition that the olfactory was situated in that lobe, though none of them as clearly as in the case before them. He mentioned several cases in which the same symptoms had been observed.

Dr. HUGHES BENNETT mentioned that in several cases which he had observed even when there was no anosmia the sense had always diminished in intensity after the exaggerated sensations, and the same remark applied to aberrations of other senses.

Dr. WILLIAM ANDERSON mentioned a very similar case in a schoolmaster who ultimately died, and in whom a tumour was found in the same situation.

Surgical Intervention in Acute Obstruction.—Dr. B. W. RICHARDSON then read a paper raising the question as to the proper moment for surgical intervention in case of acute obstruction of the intestines. After narrating an illustrative case, he summarised the object of his paper as follows:—(1) That in all cases of obstruction, efforts to relieve by milder methods, purgatives, enemata, massage, etc., might be carried on until tne appearance of stercoraceous vomiting; (2) that as soon as this symptom was perceived there should be no hesitation in opening the abdomen; (3) that obscurity of diagnosis was no bar to operation in the presence of fæcal vomit: (4) that clinical experience showed that there was very little chance of recovery once this symptom had set in; (5) that fæcal vomiting was to be regarded as something much more serious than obstruction.

* * * *

GLASGOW SOUTHERN MEDICAL SOCIETY, Thursday, January 24th, 1889 (John Glaister, M.D., in the chair). **The Superficial Injuries of the Eyeball.**—Dr. A. MAITLAND RAMSAY read a paper on injuries affecting the conjunctiva and cornea produced by (1) foreign bodies, (2) "fires," (3) abrasions and uncomplicated wounds of the cornea, (4) burns and scalds and (5) gunpowder accidents. Practical hints were given regarding points of diagnosis and treatment. In reference to the transplantation of a clear cornea from the rabbit in cases of leucoma, Dr. Ramsay remarked that such an operation, no matter how much it advertised the name of the operator, was invariably calculated to end in disappointment to the patient, for even in the few cases when success had been claimed for it, the improvement had been very slight. Some discussion took place regarding the healing of the corneal wound. Dr. Dalziel held that the cells producing the cicatrix were not the ordinary white blood corpuscles but fixed corneal corpuscles, the tissue formed not being white fibrous tissue but corneal tissue with the fibres irregularly arranged. The paper was illustrated by means of diagrams and sections of the cornea shown by the microscope.

* * * *

MIDLAND MEDICAL SOCIETY (Arthur Foxwell, M.B., in the chair). **Natiform Knee.**—Dr. SUCKLING showed a child, æt. eighteen months, with a well-formed natiform knee. The mother had two children born dead; this was the third. A few months after birth the child was ill and had suffles, but no rash. At the present time the skull was of the hot cross bun type, the complexion was sallow and earthy, the lower epiphytes of the radius on each side were enlarged and the ribs nodulated. Dr. Suckling considered the natiform skull in this case, which was so marked, to be rare in infantile syphilis, but considered that when present it was pathognomic of the disease.

Horny Growths from the Skin.—Dr. HASLAM showed two horny growths from a patient, æt. fifty-two. One grew from about two inches above the upper border of the sternum; this the patient had been in the habit of cutting from time to time, when it got in the way of her dress. It was first noticed nine months ago. Both were extremely dense, and about three-quarters of an inch in length.

* * * *

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY (H. Handford, M.D., in the chair). **Rupture of the Popliteal Artery: Successful Transfusion.**—Dr. ANDERSON described a case of incomplete rupture of the popliteal artery, in which transfusion had been successfully performed. The patient was a boy, æt. fifteen, who had his leg crushed between the trams, and had not been able to move his leg from that time. Soon after his admission, an incision was made over the fluctuating part of the swelling, and a drainage tube put in. Some turbid serum and dark clot escaped, but no pus. A week afterwards furious arterial bleeding occurred from the wound, and the boy became blanch, cold, and pulseless. Restoratives were administered, and next morning an incision was made, and the popliteal artery was found partially ruptured just at the origin of the superior branch. Both ends of the vessel were ligatured. The vein was intact; very little blood was lost, but the boy passed into an alarming state, with the same symptoms as on the previous day. Eight ounces of the same solution (two grains of chloride of sodium to the ounce of warm water) was then injected into the median basilic vein of the other arm with striking benefit. The patient rapidly rallied from the operation, and the wound healed without further accident.

Intrathoracic Pressure.—Dr. C. H. CATTLE exhibited a man, æt. forty-seven, with symptoms due to intrathoracic pressure, supposed to be due to an aneurysm springing from the concavity of the aortic arch. Of this, however, there were no external signs beyond slight chillness and pulsation in the first intercostal space near the left border of the sternum, and accentuation of the second sound in the same situation. He suffered from dyspnœa on exertion, accompanied by

stridulous breathing and from attacks of hoarse paroxysmal cough. The breath sounds over the left chest were naturally futile. These symptoms could be accounted for by pressure on the trachea left bronchus, and left recurrent laryngeal nerve.

Semi-confluent Small-pox.—Dr. BOOTBRYER read notes of a case of semi-confluent small-pox in a woman seven months pregnant, who was subsequently delivered of a perfectly healthy child at full term. The woman had been exposed to infection only on the thirteenth or fourteenth day previous to onset.

Poisoning by Citrate of Caffeine.—M. GERATTY said he had attended a lady who, suffering from migraine, had taken a desertspoonful (equal to 200 grains) of pure citrate of caffeine in mistake for the granular effervescent form of the drug. Seeing her after the accident, she only complained of the nauseating taste. M. Geratty induced her to eat a little porridge. This act was immediately followed by nausea and faintness, and within a quarter of an hour after taking the poison, there was grave depression with extreme pallor semi-unconsciousness, and complete muscular relaxation, pulse slow, soft, and readily compressible, restoration slow and sighing. An early emetic ($\frac{1}{12}$ grain apomorphine) was given, and acted speedily and completely. Small quantities of brandy, warmth, and the recumbent position, were ordered. A well-marked rigor was observed about an hour from the first taking of the poison. Consciousness was completely recovered within an hour and a half. Faintness, nausea, and other symptoms, gradually passed off during the day.

* * * *

SUFFOLK DISTRICT MEDICAL SOCIETY, UNITED STATES. **Two Cases of Laparotomy for Extra-uterine Pregnancy.**—DR. M. H. RICHARDSON reported these cases. *Case 1.*—Tubal pregnancy. Rupture during the third week and hæmorrhage into the abdominal cavity. Laparotomy. Recovery. This case illustrates the difficulty often met with of making a diagnosis in certain obscure affections of the abdominal cavity, as well as the advantage in such cases of early operative measures.

Mrs. P——, æt. thirty-seven, was in good general health. No catamenial disturbances. Married when seventeen years old. Had a miscarriage at the sixth month about a year after marriage, and since then has never been pregnant until present time. Last flow three weeks ago. On Sunday, July 1st, having been in usual good health, she was seized suddenly in the night with severe pain in lower abdomen. Some relief the next day and then a return of pain with feeling of faintness, nausea and vomiting. Bowels moved three days before. On entering the hospital she had an expression of anxiety. Temperature 97°; pulse 80 and weak. Abdomen not disturbed. Some dulness on percussion in right iliac region, but no resisting tumour to be felt. On vaginal examination tenderness to right of uterus with an indistinct tumour close to uterus. The diagnosis was considered doubtful, although hæmorrhage from some unknown cause was considered probable and an operation was commenced. Incision was made in the right semilunaris. On opening into the abdominal cavity there was a spurt of arterial blood, so profuse that it was suggested that I had cut an abdominal aneurysm, but clots soon followed. On examination the right Fallopian tube was found with an enlargement the size of a large olive, in which there was a rent admitting the finger-tip near the ovarian extremity, through which the blood was rapidly flowing. The tube with its contents and the ovary were easily brought up and Tait's knot applied, after which the whole was removed with the actual cautery. The wound was then closed and dressings applied. The patient made a rapid recovery and was discharged well, August 8th. This was a case of ruptured tubal pregnancy. She would have died of hæmorrhage in a short time if nothing had been done.

Case 2.—Extra-uterine pregnancy; death of fœtus at about the sixth month; laparotomy at tenth month; recovery. Mrs. B——, æt. twenty-six, had always been well. Married nine years and had never before been pregnant. About Sept. 1st, 1887, she began to flow every day. About October 12th she began to have nausea and vomiting which was persistent and severe. Since there have been monthly disturbances with "quite a show most of the time." Felt motion about fifth month. After August 1st, movements continued two months and then stopped. Twice she was apparently going to be confined but nothing came away. There was a large tumour of the abdomen, fluctuating and symmetrical. Vaginal examination showed that the uterus was not enlarged. June 22nd, 1888, she was operated upon at the Massachusetts General Hospital. He made an incision in the linea alba, through which he came down upon a vascular tumour with an apparent muscular wall and apparently everywhere adherent. An incision was made into the mass until he came upon a cyst, in which he could unmistakably feel the parts of a large fœtus. The cavity of the tumour contained a large quantity of a chocolate coloured fluid. The placenta was found to be placed with its centre opposite the bifurcation of the abdominal aorta, and was everywhere adherent to the intestines. It was soft and friable and a large portion of it was removed. Drainage was secured through the posterior cul-de-sac into the vagina. The patient made a good recovery.

DR. J. W. ELLIOTT: In this class of cases the mortality is high because there is danger of septic infection. The patient is usually infected before the operation is done. I would like to ask what was the final result in the second case?

DR. RICHARDSON: There was a very small sinus at the end of the abdominal wound. The vaginal tube was left in a few days. There was constant irrigation. The temperature immediately fell, and remained a degree or two below normal.

DR. S. N. NELSON asked how much, if any, of the sac was removed?

DR. RICHARDSON: None of the sac was removed, and only about two-third or one-half of the placenta was removed. Any further attempt at removal would have been bad practice. He would like to ask Dr. Elliott if he means auto-infection when the fœtus is dead.

DR. ELLIOTT: There are classes; (a) when the fœtus dries up and becomes stone, when generally there is no reason to interefere; (b) when the fœtus becomes macerated. In this class I do not know what *starts* this course, but infection comes and death by septicæmia. They are favourable if the sac can be opened without opening the general peritoneal cavity.

DR. JOHN HOMANS: The point of these cases is, early recognition, then operate, and the high mortality would be lessened. It is doubtful if there is a true abdominal pregnancy. They are either tubal, tubo-ovarian, or tubo-uterine.

DR. NELSON said that he had seen a case rather recently that was somewhat similar to Dr. Richardson's case 1. The patient was about thirty-five years old and the mother of two children. She had not been pregnant for seven years, since when menstruation had been irregular. She suffered from indefinite abdominal pains with nausea and sinking at the stomach. There was a slight uterine flow, which for the most part confined her to bed for four weeks prior to death. The breasts were soft and flaccid, the abdomen slightly tender on pressure, the uterus somewhat enlarged and slightly retroverted, but easily movable. No enlargement to be felt about the uterus by very careful examination, and extra-uterine fœtation was dismissed from the discussion. She seemed to improve gradually until, the night before death, she was seized with the most excruciating pains, resulting in collapse. When seen she was *in extremis*. The autopsy showed the abdomen filled with clotted blood, which had escaped from a ruptured sac of extra-uterine fœtation in the right iliac region. This, on dissection and removal, was found to have originated in the fimbriated extremity of the right Fallopian tube. The sac was about 2½ inches in diameter and contained a fœtus about four inches long.

DR. RICHARDSON, in closing the discussion, said that Tait has reported thirty-five cases of operation for extra-uterine pregnancy, with two deaths and a number of viable children. In an acute abdominal case, when the woman is in a serious state of collapse, with low temperature, there is probably hæmorrhage which requires interference; with a high temperature, there is probably perforation, and again interference is necessary. Do not delay at all.

* * * *

OBSTETRICAL SOCIETY OF PHILADELPHIA. **Tubal Disease a Primary Cause of Intestinal Obstruction.**—DR. JOSEPH PRICE read a paper on the above. In reporting cases he had repeatedly called attention to the frequency of adhesions occurring between the uterine appendages and some part of the intestines, and his present purpose was to emphasise the importance of recognising the danger of obstruction of the intestine arising from inflammatory conditions of the pelvic viscera. In the cases operated on the past year, in more than 15 per cent. there were noted "dense, firm adhesions" between the intestines and uterus and appendages, malignant cases not included. In every case, with one single exception, the inflammatory conditions causing the adhesions apparently originated in the uterine appendages. First, as to form or kind of obstruction likely to occur. The inflamed serous surface of the diseased tube or ovary, coming in contact with a loop of intestine, or an edge of omentum, provokes inflammation there, and with characteristic promptitude these surfaces cohere. If the process is not severe and of slight duration, these adhesions may disappear as promptly as they occurred, by the enormous absorptive power of the peritoneum, hastened by the mild influence of the peristalsis of the bowels. If, however, the inflammation is severe or assumes a chronic condition, these adhesions gain in extent and strength and give rise to all the variety of conditions classified by Treves as "strangulation by bands." In most cases where these adhesions occur there is a history of constipation. It is probably due as much to the pain caused by defecation as to interference by the condition. Again, the pain is often

so great as to mislead the physician into thinking that a more virulent inflammation exists than really does. But the pain is not always proportionate to the amount of mischief. I have seen cases in which a mere omental adhesion has caused most agonising pain. For instance, I recently saw a case in consultation, a woman who had had the appendages removed for backache some time before, and who suffered excruciating pain, especially on defecation. In this case the only lesion found was the omentum firmly adherent to the original incision. The omentum here was much elongated, and the transversed colon was dragged below the level of the umbilicus. In like manner I have seen the omentum adherent over the entire pelvis, dragging the transverse colon so out of place that a twist or kink of the bowel could be very easily formed. It is not at all rare to find the vermiform appendix glued fast to the uterine appendages, while almost any loop of the small intestines may become adherent to the inflamed pelvic viscera. As I have said, these adhesions vary in extent and density from those that will tear like wet tissue paper to those so well organised that it requires the scissors to release them, and it is not rare in pus cases for the bowel to be almost gangrenous about these points of adhesion and, in fact, to tear through. That adhesions do not cause complete occlusion at the time of their formation oftener than they appear to is no reason for regarding them lightly, for Mr. Treves tells us in the series of cases he studied that the average duration of the interval between the causation and the obstruction was three years; the shortest period being five weeks and the longest twenty-one years. In view of these general considerations it is hardly necessary to insist upon the release of the intestines wherever and to whatsoever extent adhesions exist. For if the surgeon leaves adhesions when he closes the abdomen, he leaves a probable cause of future serious trouble.

DR. WILLIAM GOODELL said that his experience in ovariotomy led him to say that it is a mistake to postpone the opening of the bowels to a late period. He used to follow the old plan of not giving a cathartic until the eighth day, but he was confident that he had had death result from intestinal kinks, from adhesions, making it impossible for the bowels to be moved. He now gave an aperient or an enema on the fourth day, and earlier if any symptoms such as vomiting and tympanites, present themselves.

DR. B. F. BAER said that once he had kept the bowels confined after laparotomy, but now he had them moved on the second or third day, rarely as late as the fourth day. Allowing a pint of warm water to flow into the rectum facilitates the passage of flatus and fæces. He had a case fours years ago in which very serious collapse occurred at the end of the second day. Stercoraceous vomiting set in and large quantities of flatus were passed by the mouth, but none by the anus. These symptoms were thought to be due to obstruction, and reopening was considered, but not done. The patient recovered, although she did not pass flatus for five days. Should such a case occur again he would open the wound and would have the endorsement of most operators for so doing. Large doses of salines are advised in such cases, but he wondered if there was not some danger of rupture of the bowel in these cases of adhesion after serious operations, and he related a case. Dr. Price had referred to two cases where he reopened the abdomen for pain, and found the omentum adherent to the line of incision. He knew of no better way to prevent this accident than the early use of laxatives.

Fixed Uteri.—DR. WM. L. TAYLOR read a paper on fixed uteri. In looking over his case book he found the remark, "uterus fixed," so often noted, so often underscored, as much as to say "here again," that he fain would ask how many of these cases were, in their inception, recognized as cases of peritoneal inflammation? In a number the note is made, "patient had attack of inflammation of bladder." "Inflammation of bowels" has been of alarming frequency, whilst "congestion of the liver" makes him wonder at the special degree of sensibility of that organ in women. In a series of cases where the lymph deposit seemed to be the most diffused, a positive history of an active and acute inflammatory trouble could not be obtained. There was only the history of a continued abdominal pain and tenderness, dating from an abortion, from heavy lifting, seldom from normal labours, and presumably never from gonorrhœal infection; seldom—I might say never—have I had perfect success in my efforts to trace the cause to this infection. The history of the husbands, as to the existence of a gonorrhœa or gleet, at the time of commencement of a pelvic trouble, is, in the vast majority of cases, worse than uncertain. In several of the subacute cases the only ascribable cause appeared to be indirectly, if not directly, the effort to prevent conception. Freedom from the possibility of, at least, paternal cares, leads to an amiable weakness, and coition follows coition in quicker succession than the law of conservatism would recognise, and, plus the menstrual congestions, which now even anticipate, without the restful periods of pregnancy and lactation, congestion and inflammation of the peri-uterine tissues follow. That this is as immediately the cause of the fixed uteri, the thickened and enlarged ligaments and tubes, and tender ovaries, as is gonorrhœal infection, even in prostitutes, I am inclined to believe. Where the deposits of lymph were more localised or larger in quantity, seeming as if it had been poured out quickly, and had by gravity centred itself around the uterus, there were histories of acute, well marked attacks of cellulitis or peritonitis. The causes were difficult labours with badly lacerated cervices, these lacerations extending through into the cellular tissue; and also criminal abortions. In these cases, how often traumatism and how often septic poisoning was the exciting cause it is impossible to say. Catching cold while menstruating, falls, and various other accidental causes were among the number. The average physician, as soon as the patient is up out of bed, shakes himself by the hand and says, "I have cured my patient." But he hasn't! There is still the important sequel to deal with, the lymph deposits. In fully three-fourths of all the cases the body of the uterus has become fixed in retroflexion, even in multipara. Just as soon as the uterus feels the stimulus of congestion or inflammation of surrounding tissue, it becomes turgid and heavy, and sinks decidedly lower in the pelvis until the cervix is near the vulvar orifice, and following the curve of Carus, the fundus is retro-displaced. Here it is, as it were, frozen in, fixed immovably. All around it is a mass of inflammatory lymph, becoming more dense and resisting as organisation advances. In the centre of this the sound probably indicates the uterine body with a measurement of 3½ inches. The cavity is tender and the cervix softened, congested with venous blood. Now this deposit varies greatly in quantity as the inflammation has been, by judicious treatment or by nature alone, limited or allowed to involve a great extent of peritoneal surface. The possibility of determining the amount of lymph deposit and the degree of fixation by bi-manual examination seems to me to be one of the few certainties in gynæcological practice. A uterus which is low in the pelvis and which cannot be raised to the normal line, and a fundus which is retroflexed and cannot be reposited, with the other evidences, bi-manually, of thickening and deposit, cannot but point to the certainty of previous inflammation. A sterile uterus and a fixed uterus seem to be almost synonymous.

The need of shortening attacks of pelvic peritonitis, aborting them if possible, can only be appreciated by those called upon frequently to treat the sequelæ.

If these are thoroughly treated the amount of lymph thrown out is small and probably will be absorbed almost as rapidly as it was thrown out. But we meet a case which was treated by "the other doctor around the corner," and the uterus and its appendages are imbedded and immovable. Now what are we to do? The great object is to get rid of as much of this effused matter as we possibly can. The older and more thoroughly organised this becomes the less chance there is of rapid and complete absorption. So the normal is, commence early. It is going to do one of three things: undergo absorption, break down and form pelvic abscess or become organised, acquiring an adventitious circulation. In a case of recent or comparatively recent deposit he commences treatment by correcting the digestive tract, getting the stomach, liver and bowels in better condition and surface circulation is stimulated by warm baths and frictions. He then gives mercuric chloride, with iodide, commencing with small doses frequently repeated and gradually increasing the dose and lengthening the time. Locally he relies upon the abdomino-vaginal galvanic current and gentle or more decided uterine massage, as there is great or little tenderness. This uterine massage he prefers in cases of long standing, where the tenderness has disappeared, but still used carefully where there is tenderness, he finds it beneficial. Every other day, or twice a week, make steady pressure upon the fundus of the uterus with the index finger of the left hand in the rectum and upon the cervix and body of the uterus with the right index finger in the vagina. This pressure is kept up for two or three minutes, gradually trying to force the body upwards and forwards. Then efforts at lateral movement for the same length of time. This massage is followed with the continued galvanic current, using the abdomino-vaginal method. For the breaking down of pelvic lymph he has not used electro-puncture, preferring the slower and as certain absorption by the stimulation of pelvic circulation. Where there is tenderness he uses the positive pole in the vagina and the negative over the abdomen for the first three or four applications and it is marvellous how rapidly this tenderness disappears. He then reverses the poles, using the negative with a ball or small crescent-shaped electrode in the vagina. These *séances*, including the massage, last for about fifteen or twenty minutes. The strength of current averages about 25 to 30 milliampéres. After this is over he frequently packs the fornix with wool, introducing a small ring pessary to kept the wool as much as possible in position. After he gains a certain amount of mobility he introduces a Smith-Hodge pessary, small at first, increasing to a more suitable size as the uterus rises to the normal line. Tincture of iodine to the fundus of the vagina.

HOSPITAL REPORTS.

ROYAL ALBERT EDWARD INFIRMARY, WIGAN.

UNDER THE CARE OF WILLIAM BERRY, F.R.C.S.I.

CASE I.—*Compound Depressed Fracture of the Skull—Trephining—Erysipelas—Recovery.* [For notes of this case we are indebted to Mr. R. S. HALL, M.R.C.S. Eng., L.R.C.P. Lond., Junior House Surgeon.]

Mary L——, of Wallgate, Wigan, æt. fifty, widow, admitted to Royal Albert Edward Infirmary, Wigan, August 19th, 1888. A woman of intemperate habits, who, a few months previously, was an inpatient at this hospital suffering from a wound of the scalp, which was followed by erysipelas. Patient stated that on the previous evening she had a quarrel with her landlady, who struck her on the head with a lading-can which was at hand. She was taken to a medical man in the town who, seeing the nature of the injuries, advised her to go into hospital. This she did the following day, as above stated. On admission she was perfectly conscious, spoke rationally, and walked into the wards; pupils normal. On examination of the head there was found on the left side a contused wound, about 1¾ inches in length, of an elliptical shape, situated about two inches above the ear, extending down to the bone, which lay bare at the bottom of the wound, the outer table being depressed and fractured. Patient also had a depression on the forehead, the result of an injury in the mill twenty years ago. On the evening of admission she was anæsthetised (CH Cl_3 being used) and trephined, when the fracture was found to be about an inch in length, and the inner plate much depressed. The spiculæ of bone were removed and the wound packed with iodoform and oiled lint.

August 20th: Wound dressed and looking well.

August 21st: Wound is very foul looking; no discharge. Temp. 103° F. Erysipelas commencing in the scalp. Lead and carbolic dressing applied. Given liq. ferri perch. in ʒ js. doses ter die.

August 22nd: Erysipelas extended all over scalp and face, which is very much swollen.

August 26th: She is much improved. Erysipelas subsiding; wound looks healthy, and discharging freely; tongue covered with thick white fur; bowels constipated. Purgative given.

September 1st: Erysipelas has entirely disappeared; wound covered with healthy granulations. Temperature normal. Appetite good.

From this date patient gradually regained strength, the wound slowly granulating up. One or two small spiculæ of bone came away at different times, and she was discharged on October 21st with the wound completely healed.

Remarks by Mr. Berry.—This case was interesting owing to the appearance of the depressed bone, which appeared to be external plate only. Trephining at once, however, removed the doubt, and showed depression of internal plate. Had we waited for symptoms we should probably have had inflammation of the membranes and suppuration, with an unfavourable termination. The erysipelas was certainly a serious complication, but no more severe than what we see in ordinary scalp wounds.

CASE II.—*Ovarian Tumour—Ovariotomy—Death.* [For notes of this case we are indebted to Mr. J. A. BARNARD, M.R.C.S. Eng., and L.R.C.P. Ed., Senior House Surgeon.]

Mary H——, Wigan, æt. fifty-seven, widow. Admitted Dec. 4th, 1888. *Family History:* Father died six years ago of Jaundice. Mother died eleven years ago of cancer of womb. Three sisters—two died young, one living. *Previous History:* Married at twenty-three. Has had three children—two living. Says she had had gastric fever in 1870. No other serious illness. Has lived a hard life. Menstruation has been fairly regular, and ceased ten years ago. She first noticed a swelling on left side of abdomen some nine months after the menopause, about the size of a small hen's egg. Says that she had severe pain at the commencement. It grew rapidly for three or four years, but not much lately. Measurement five years ago, thirty-six inches over umbilicus; to-day (December 5th), thirty-three and a half inches.

This case was sent into hospital by Dr. Brady, of Wigan, who had attended the patient at intervals for two years. He diagnosed ovarian dropsy. She had periodically severe pain (gastrodynia) and vomiting, which was relieved generally by hypodermics of morphia and bismuth mixture. After her admission she suffered from vomiting and pain, which was attributed to reflex action from pressure of the tumour. Ingluvin in ten-grain doses was administered. A mixture of chlorodyne and liquid ext. cascara sagrada was given for the pain and constipation. An enema was administered on the second day. Milk diet; Brand's essence of beef, and four ounces of brandy daily.

Urine: sp. gr. 1025; no albumen, but a trace of bile. Temp. 99.4° F.
December 6th: Temp., morning, 98.4° F.; night, 99.2° F.
December 7th: Temp., morning, 98° F.; night, 99° F.
December 8th: Temp., morning, 97.8° F.; night, 98.8° F.
December 9th: Temp., morning, 97.6° F. (morning of operation.)

On Sunday, December 9th, the patient was placed on the operating table, and a mixture of alcohol, ether, and chloroform, was administered. All the instruments, sponges, etc., were in carbolic lotion. An incision about two inches in length in the median line was made, and the cyst exposed. The fluid (120 ounces) was drawn off with Spencer Wells' trocar. The pedicle was clamped and transfixed, and ligatured in two halves with strong silk whipcord. There were a few troublesome adhesions which delayed the operation slightly, the hæmorrhage being also troublesome. A Keith's tube was introduced, and the wound sutured in the usual manner, and dressed with wood wool pads.

The operation occupied about one hour. The patient lived twenty-four hours, the treatment being ice by the mouth and nutrient enemata of beef tea and brandy every four hours. Suppression of urine occurred—only three ounces being drawn off with the catheter. The temperature at death was 101.4°.

Remarks by Mr. Berry.—This patient appeared to be a favourable one for operation, and the operation was performed in the ward where she was to be nursed. The operation was somewhat tedious owing to pelvic adhesions and troublesome hæmorrhage, This was checked by washing out with moderately-warm water. She appeared to rally from the operation, but became comatose early next morning from the shock and suppression of urine. Perhaps a longer stay in the hospital before operation was desirable.

Surgical Aids and Appliances.

118.—APPARATUS FOR ILLUMINATING AND EXAMINING ANATOMIC SPECIMENS.—TROUVE'S "ECECTROFRAISE."—LAILLIER'S APPARATUS.

ACCORDING to Dr. G. Beck's *Illustrirte Monatsschrift der Aerztlichen Polytechnik*, No. 1, 1889, p. 18, at a recent meeting of the Paris Odontological Society, Professor L. Serres has read a paper in

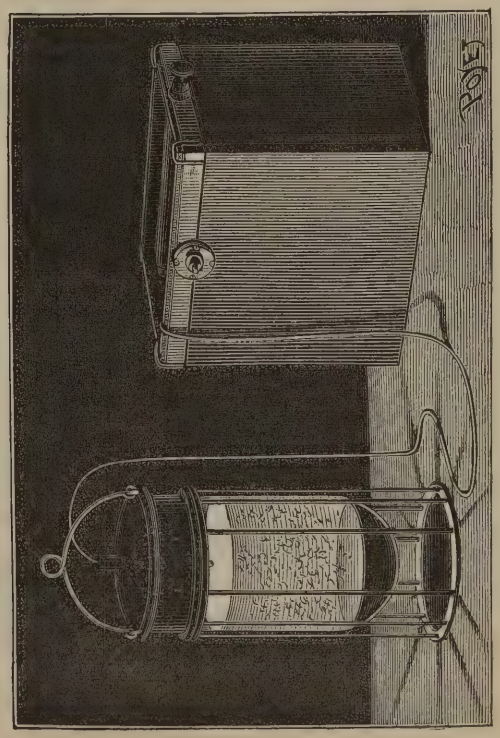

FIG. 1.

which he describes (*a*) an apparatus for illuminating and examining anatomic specimens suspended in water (fig. 1); (*b*) electromotors

adapted for use in dental practice; and (*c*) Dr. Laillier's apparatus. As is known, in former times the electromotor machines in general were constructed on the principle of an electro-magnet (*e.g.*, Froment's apparatus), but now-a-days electromotors invariably represent nothing else than dynamo machines worked by means of a constant current. Hence they work in a two-fold way: when set in rotation mechanically, they serve as a source of electricity; contrariwise, when an electrical current is allowed to pass through the induction-bobine, a mechanical force is produced, the machine becoming a motor. The machines described by Professor Serres are Trouvé's motors constructed after Gramme's system. They consist of two concentrically arranged rings, of which the outer one is immobile, and represents an inducing electro-magnet; while the mobile inner ring, connected by means of a conducting wire with the source of electricity, serves for the circulation of an induced current. The motors, as constructed by Trouvé, vary in their weight from fifteen kilogrammes to ninety grammes, and in their force from one-horse power to $\frac{3}{100}$. A motor weighing ninety grammes, and supplying $\frac{3}{100}$ horse power is said to be fully sufficient for all odontological purposes. A motor of the kind mounted with a dental drill (*fraise*), and hence bearing the name of an "*electro-fraise*" (fig. 2),

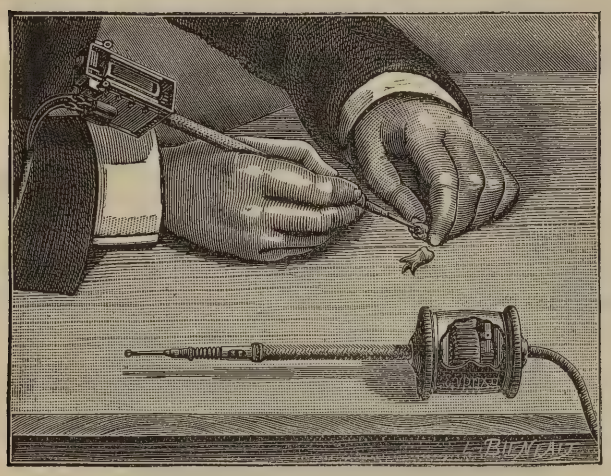

FIG. 2.

weighs not more than 150 grammes, and is said to be worked as easily as a pen or lead pencil.

Dr. Laillier's apparatus (fig. 3) is a non-electrical "*fraise*"-motor,

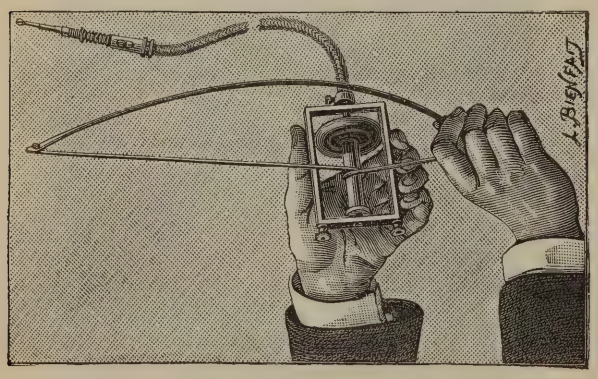

FIG. 3.

constituting a very useful dental contrivance. It consists of (*a*) a revolving axle, bearing a fly wheel, and connected with a dental drill; and (*b*) a metallic bow, furnished with a wire wound round the axle. On playing the bow to and fro, the drill can be brought into a regular motion.

Medical Miscellanea.

THE subject of our next illustration will be Arthur Edis, Esq., M.D.

* * * *

The next meeting of the American Medical Association will commence at Newport, Rhode Island, on June 25th, 1889.

* * * *

An International Congress of Physiology will be held at Basle, September 10th, 1887.

* * * *

We regret to hear that Sir Thomas Crawford's term of office will shortly expire.

* * * *

The Orthopædic and Spinal Hospital, Birmingham, will in future have the word Royal prefixed to it. The Queen has graciously given £50 to the funds and permission to use the title.

* * * *

The new buildings intended for the Medico-Chirurgical College, of Philadelphia, were opened and inaugurated with great *éclat* on January 26th, 1889.

* * * *

A beautifully illuminated address has been presented to Dr. Mapother, with an illuminated album, as a token of esteem from his professional brethren in Dublin. Deep regret was expressed at his leaving them.

* * * *

Two deaths have been recorded lately under chloroform; one in an obstetric case, and the other at the Crumpstall Workhouse, both in Manchester.

* * * *

Dr. Weir Mitchell has been appointed to a new chair, that of Diseases of the Mind and Nervous System, in the Philadelphia Polyclinic and College for Graduates in Medicine.

* * * *

The annual report of the Royal Maternity Charity states, that of 3,604 poor women who had been attended during the past year, only 11 had died, and of the children 3,521 were alive. Sir John Lubbock has consented to preside at the forthcoming triennial dinner in April next.

* * * *

We have received a new paper entitled *Medical Topics*, which has a novel feature about it—viz., the publication of a medical "black list," giving the names and addresses of persons about whom information is wanted.

* * * *

The *St. Petersburg Gazette* believes that the question of permitting ladies to practise medicine in Russia has been definitely settled in an affirmative sense, with the stipulation that ladies shall only attend on adults of their own sex and on children of both sexes.

* * * *

By the will of Dr. John Chapman, formerly a West-end practitioner, a sum of £56,000 is, after the payment of a legacy of £10,000 to his executors, to be divided between the following three charities: The British Medical Benevolent Fund, the British Home for Incurables, and the Orphan Working School.

* * * *

The Council of King's College have established a chair of Neurology, in which Professor Ferrier has been elected. It is hoped a Neurological Laboratory will be established as soon as the Royal Microscopical Society vacate their present apartments in the College.

* * * *

The third Russian Medical Congress was held at St. Petersburg on January 16th, and seven following days. It was opened with great solemnity by Professor Botkine, who said the numbers present at the first congress was 500, at the second 1000, and at the third 1500. Dr. Erissmann, Professor of Hygiene at Moscow, was elected president of the congress. There were eighteen sections, and a number of papers were read.

The following office-bearers have been elected in the Wigan Medical Society for 1889: *President*—R. F. Woodcock, Esq., M.R.C.S. Eng., and L.R.C.P. Lond. *Committee*—E. H. Monks, junior, C. E. Brady, W. C. Barnish, Nathan Hannah, and J. B. Stuart, with the ex-president and hon. sec. *Hon. Treasurer*—E. H. Monk, junior, L.R.C.P. and L.R.C.S. Edin. *Hon. Secretary*—Wm. Berry, F.R.C.S.I.

* * * *

At a meeting of the Sanitary Assurance Society is was resolved on the proposal of Dr. Rutherford, seconded by Surgeon-General Cornish, "That Dr. Farquharson, M.P., be asked to introduce the Sanitary Registration of Buildings Bill on the opening of Partiament, and to take steps to obtain as early a date as possible for its second reading; and that Sir W. Guyur Hunter, M.D., M.P., Sir Henry Roscoe, M.P., F.R.S., and Dr. Cameron, M.P., be again asked to join Dr. Farquharson in introducing the Bill; and that as soon as the Bill is printed, and in the hands of the House of Commons, the President of the Local Government Board shall be asked to receive a deputation in support of the Bill."

* * * *

The following circular has been issued, signed by several leading members of the profession, to the presidents of the branches of the British Medical Association, with a view of eliciting an expression of opinion from the members of the Association:

"It is universally admitted that the *British Medical Journal* is at present ably edited, and that, while it is a great financial success, it is a repertorium of a vast amount of valuable scientific information.

"At the same time it is believed by many members of the profession that the best interests and the honour of the Association would be greatly promoted by a change in the character of the Journal.

"An opinion has for several years been widely held that the lines on which the Journal is now conducted, which are similar to those of proprietary Journals, with anonymous articles and reviews and multifarious advertisements, are not suitable for the organ of our Association, for the sayings and doings of which our members individually are responsible.

"It is felt that the Journal should be a faithful exponent of the proceedings of the Association in all its departments, while presenting a record of contemporary professional work elsewhere; but that anything beyond this, whether articles, reviews, or annotations, should have the authors' signatures appended, as indicating the actual authority of the communications. The character of the advertisements also should be more carefully controlled than at present, and especially all announcements of secret remedies should be excluded.

"It may be objected that such a change in the Journal would involve some pecuniary loss. But our members are now so numerous that the annual subscriptions, together with income from other sources, would cover all current expenses. And it may be remarked that our individual self-respect is a matter of higher moment than flourishing finances.

"It is proposed, in the first instance, to address the Council of the Association requesting them to consider this important subject, and should it be deemed necessary, to summon a special general meeting in London. But before taking such a step it seems essential that there should be some guarantee that the proposed reform would be favourably regarded throughout the country. And we venture to ask that you will ascertain, as soon as may be, the feeling of your Branch upon the subject, and communicate the result to the Honorary Secretaries."

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the EDITOR, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16*th of the month.*

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

"TAKE YOUR MEDICINE."

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—As is only too well known, children and infants frequently refuse to take medicines, however palatable they may have been made. A great deal of trouble may be saved I find, by fixing the cheeks firmly with the finger and thumb of the left hand, whilst the spoon is inserted with the right. By this method, which I first observed practised by a young married lady recently, the first essential in the act of deglutition is provided for, *viz.*, a fixed point for the pharyngeal muscles. Ordinarily this provision is effected by closing the mouth; and there cannot, I think be any doubt, that the prevention of the natural process by the pressure of the spoon, leads, in great part to the struggle to avoid taking medicine. When the approximation of the lips is prevented by the firm forward pressure of the finger and thumb, medicine may be poured into the pharynx without fear of its being spat out, and the most refractory child will, as a rule discreetly swallow it.

The practice of nipping the nose, should I am sure, be strongly condemned, because of the risk incurred of forcing the medicine along the Eustachian tube.—I am, sir, yours faithfully,

January 29th, 1889. C. R. ILLINGWORTH, M.D.

ON GOING TO SLEEP.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Mr. Brown's comprehensive letter (PROVINCIAL MEDICAL JOURNAL, January 1st) upon "Animal Alkaloids" throws some light upon the causes of the recurrent and periodical return of a disposition to sleep, but I would respectfully submit that it does not appear to cover the whole of the inquiry. Thus, it does not explain the irresistible desire for sleep that comes over one at inconvenient times, apart from fatigue or over-exertion, and would seem to be dependent upon the condition of the cerebral circulation. I would illustrate my meaning by stating my own case. If I take up a book, be it of light or grave literature, and attempt to read it in a reclining position, *e.g.*, leaning back in my chair, I inevitably fall asleep in a short time. The same thing occurs to many persons in railway travelling. Whereas, if I resume the upright position at my study table, I may read for hours without becoming drowsy. How is this to be explained? The theory that explains sleep by a diminution of supply of blood to the brain does not, to my apprehension, meet the case.—I remain, Sir, your obedient Servant, "SLEEPY-HEAD."

London, February 10th, 1889.

"QUASI-HYDROPHOBIA."

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—It is needful to make an elucidatory remark or two relative to my contribution in last number on what might be called *Aqua-Bibitory Disease*, in which I detailed a case where the symptom which gives hydrophobia its name was absent. Such cases, it is demonstrable, occur; and while they resemble hydrophobia more or less in other characters, want this one, so that they cannot be classed under that recognised form of disease.

Two of the cases I adduced were, as I hinted, collateral, and intended to illustrate a feature of the case detailed—viz., the supervention of a serious disease upon the successful removal of some local one of less moment. This is a highly practical consideration, though no new one, for us to bear in mind in endeavouring to cure local affections, and particularly applies where these are of long continuance and inveterate. There existence is, then, often a safety-valve for the constitution and, as the cases mentioned show, may be the very condition of *life*. In the

MS. these cases were bracketed, to show they were not instanced as in any way hydrophobic. In one of them, by error, it is said the patient died "hydrophobic," when it should have been given "apoplectic." The hydrophobic character of this case might seem very inexplicable; and, therefore, I have felt necessitated to make this correction for any who may have thought the paper deserving of their attention. The police case cited was, like all else, treated as briefly as possible. I should explain that here we had together a violent nervous and, indeed, mental disorder—though in this case manifested in "thirst for blood," or suicide—and a bite from an animal. These had not been in the least connected, but the fact I notice is that they were both present, and that no other cause was offered for the anomalous disease. Hence, I think the theory of aqua-bibitory disease explains it, and that, had we exact knowledge as to this, it would have been found this man discovered *some* peculiarity as to water-drinking. He had not the aversion of hydrophobia, evidently, or he would have been regarded as a case of this disease, and his strange affection at once explained. He would then, no doubt, have been treated less as a police than as a medical case.

How is the supervention of his form of frenzy to be explained but according to my hypothesis? And here *there had been* a bite; yet it was not *hydrophobia*. Is it not likely the cause which leads to fearful results under this name would produce *some* effects where for any reason failing to lead so far? And would not such results be akin to hydrophobia? If so, we have to expect the kind of malady I have described? and, when one finds actual cases, there is no existing class of disease to which they belong. Here, however, are diseases, nevertheless.

Cardiff. CHAS. FOX.

THE DUBLIN BARRACKS.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Respecting the question of the unhealthiness of the Dublin Barracks, I beg to ask your attention to an article in the *Builder* of January 19th last by a professional architect on the condition of the stone of which it was originally built. He states that the *bad health* of the troops is due to the foul air given off by this stone, now in process of decay or degradation. It is called "*calp*," *or mudstone*, an unconsolidated species of superficial formation, probably estuarine, which is very *hygroscopic*, and has now been for years absorbing impure moisture and water, and is now slowly settling down into decay of its original constituents. If such should be the case, then a *mineralogical inspection* should be made of the walls, below and above ground, and these bored into, and the *cores* of stone examined by architects. After confirmation of the unsanitary cause, then nothing would remain but *demolition* of the building, as it could not be occupied or used for any other purpose. The writer also says that a large part of *old Dublin* on the level of the river is built of like material, which is now decaying by moisture, and becoming degraded into rubble or unformed stone. It is evident that Dublin has not yet secured the advantages of "Removal of Unhealthy Dwellings Acts," which has benefited Birmingham, Manchester, and Liverpool so much.—Yours sincerely, "POLYORCETES."

Edinburgh, February 10th, 1889.

☞ NOTICES OF DEATHS, BIRTHS, AND MARRIAGES, occurring in the families of our subscribers will be inserted, free of charge, in the *Provincial Medical Journal* if sent, duly authenticated, to offices.

Provincial Medical Journal:

A MONTHLY REVIEW OF MEDICAL SCIENCE, LITERATURE, AND BIOGRAPHY.

VOL. VIII.] APRIL 1, 1889. [No. 88.

Our Portrait Gallery.

ARTHUR WELLESLEY EDIS, M.D. LOND., F.R.C.P.

ARTHUR WELLESLEY EDIS was born at Huntingdon in 1840, and educated at Aldenham Grammar School, Herts. After this he spent two years at the Royal Agricultural College, Cirencester, where he acquired a knowledge of Chemistry, Botany, Geology, and other kindred subjects. It was in the Veterinary Hospital here that he first developed an interest in Medicine. Having completed the curriculum, he obtained the diploma of M.R.A.C. in 1857, and after passing the M.R.C.S. and 1st M.B. of London, he studied at Vienna, Berlin, and Paris. For five years he was attached to the Hospital for Women, Soho-square, and for fifteen years has been connected with the Middlesex Hospital, first as Assistant Obstetric, and on the death of Dr. J. Hall Davis, as full Obstetric Physician.

He is now Senior Physician to the Chelsea Hospital for Women; Consulting Obstetric Physician to the City Provident Dispensary, and to the Hounslow Cottage Hospital Dispensary; late Physician to the British Lying-in Hospital. He is a Corresponding Fellow of the Gynæcological Society of Boston, U.S.A.; Fellow of the Medical Society of London; Member of the Clinical and Harveian Societies; and was last year President of the British Gynæcological Society.

Dr. Edis has largely assisted in the foundation and development of an English School of Gynæcology; his tendency leans to surgical interference in suitable cases. In his admirable presidential address to the British Gynæcological Society, he says:—"The tendency for many years past has been to advance in a surgical direction, and unquestionably much has been gained. Cases which scarce a generation ago were regarded as hopeless, over which medicine had no power, either to control the growth of tumours, or prevent a fatal issue, are now rescued from their impending fate, and restored to health and usefulness. The triumphs of abdominal surgery are still the wonder of the age. Ovariotomy alone has been the means of saving countless thousands of lives. Removal of the uterine appendages, whether in the case of bleeding myoma, or chronic incurable diseases of the ovaries or tubes, has enabled the surgeon to convert useless suffering and miserable invalids into useful members of society, able to earn their own living, or to fulfil the duties of their station with comfort and freedom from suffering. The surgical treatment of extra-uterine gestation, bold in its conception, and successful in its issue, appeals alike to the profession and the public. Shortening of the round ligaments; raising the prolapsed ovaries, and attaching them to the parietes by a plastic operation; repairing the ruptured perineum; removing the hypertrophied cervix uteri, or restoring it to its normal condition when laceration has occurred by the operation of trachelorraphy; constricting the vaginal passage by colporraphy, when it has become so lax as to cause considerable discomfort, and allow the uterus to be prolapsed even beyond the vulval orifice: all these and many other operations of a like nature may be quoted as evidence of my original statement."

Dr. Edis was not content with only being an obstetric practitioner; only last year he contested the right—and succeeded in obtaining permission—to perform ovariotomy and other similar operations at the Middlesex Hospital, the surgeons hitherto claiming these operations as theirs. Some years since Dr. Edis published a pamphlet on "Seats for Shopwomen," and directed the attention of the public to the hardships undergone by young women in being compelled to stand from 8 a.m. until 7 or 8 p.m.

His manual on "Diseases of Women" went through two large editions in a very short time. His contributions to the medical journals have been numerous, including "Lectures on Uterine Hæmorrhage," "The Influence of Obstetric Knowledge on the Mortality of Mothers in Childbed," "The Rational Treatment of Menorrhagia," "The Forceps in Modern Midwifery," etc.

Original Communications.

ON TOPICAL REMEDIES FOR DISORDERS OF THE ANUS AND RECTUM, AND IMPROVED INSTRUMENTS FOR THEIR APPLICATION.

By John Ward Cousins, M.D. Lond., F.R.C.S.,

SENIOR SURGEON TO THE ROYAL PORTSMOUTH HOSPITAL, AND TO THE PORTSMOUTH AND SOUTH HANTS EYE AND EAR INFIRMARY.

The common disorders of the anus and rectum exhibit very varying degrees of severity. Sometimes local distress, pain, and frequent bleeding necessitate surgical interference without delay; at other times, any operation appears undesirable in consequence of age or extensive visceral disease. The judicious surgeon will always select those cases which are favourable for radical cure, and in this way avoid the complications and disastrous results of bygone practice.

Now every day we meet with mild forms of these diseases, for which our patients refuse altogether to undergo surgical treatment, but they are very anxious to adopt palliative measures. Fortunately, in a large number of cases, the judicious application of topical remedies is followed by great temporary relief, and sometimes even by permanent cure.

Of course anal and rectal affections are not always mere local disorders. In many cases they are excited by general diseases and visceral obstructions, and the removal of the primary cause always demands the first attention. Respecting general treatment, great relief can often be obtained by regulating the secretions, by attention to the diet, and especially by avoiding all excesses in eating, drinking, and tobacco. Aperient and laxative remedies are frequently serviceable, but they must always be mild and unirritating in their action.

With these few remarks I shall pass to my special topic—the local treatment—and I shall briefly narrate my experience as to the best applications, and the best method of applying them.

During the act of defæcation in the healthy condition of the bowel, the blood-vessels around the orifice are distended, and slight protrusion of the mucous membrane takes place, and, whenever the muscular tension and vascular turgescence of the part are habitually prolonged and severe, the very conditions are present which promote the development of hæmorrhoidal troubles. In cases of ordinary constipation, and prior to the expulsion of hardened accumulations, some softening or lubricating agent may with great advantage be introduced into the rectum, and for this purpose I strongly recommend a smooth and creamy mixture of boracic ointment, glycerine and lanoline.[1]

In relaxed conditions of the anus and rectum, with a tendency to prolapse, prolonged efforts during evacuation distend the dilated vessels, aggravate the varicose state of the anus, and increase the local distress. Straining at stool must at all times be carefully avoided. It is a good plan to get a regular action of the bowels just before going to bed, instead of early in the morning, for then, during the repose of the night, the intumescence of the organs has time to subside. Immediately after an evacuation the anus should always be washed, and the well-soaped hand is the best instrument for the purpose. Habitual cleanliness is one of the most effective ways of preventing hæmorrhoidal disorders. The irritating secretions and mucus from the orifice of the gut are removed, and the friction tends to brace up the part and empty the distended vessels. There is no region of the body which really requires so much sanitary attention, but, even in these days of hygienic enthusiasm, it is too often the last to be cleansed.

The affection commonly styled 'piles' is in many cases nothing more than soreness and irritation of the anus, produced by daily neglect and local impurity. When the surrounding skin is healthy any ordinary soap may be selected for washing purposes. Sometimes the folds of skin around the orifice are swollen and irritable, and often external hæmorrhoids cause a great deal of irritation. In persons of a full habit a local erythema is very common, extending over the nates. The skin is red and moist, and by friction it becomes tender and excoriated. The disorder is generally easily cured by careful attention to the part every evacuation. I have used with great success well-washed soft soap made into a smooth compound with the alcoholic solution of coal tar, or the oil of Cade or eucalyptus globulus. After the lavement the part must be carefully dried with a soft towel, and dusted with a fine powder composed of carbonate of bismuth, oxide of zinc, and starch.

In cases of chronic gout, and in other constitutional derangements, an obstinate form of eczema attacks the anus and genital organs, and the tormenting itching which attends the disease causes persistent scratching and excoriations. Sometimes the skin becomes infiltrated and fissured in the direction of the normal radiating folds. This disorder cannot, of course, be treated apart from the constitutional condition with which it is associated; but the daily use of the soap I have mentioned is often followed by remarkable benefit. The drying powder may then be applied over the part, or a little of the boracic ointment gently rubbed in.

The local treatment of prolapsus ani and hæmorrhoidal disorders is a matter of daily importance. In acute inflammatory affections of the anus rest in bed should be maintained, and the patient will be much relieved by sitting two or three times a day in a hot carbolised bath.

In all cases requiring washing and irrigation, I recommend the use of a very convenient contrivance. It consists of a metal pan with a deep well in the bottom, and it is supported on short legs. The patient sits on the side of this well, so that the anus and genital organs can be completely bathed. It is especially serviceable in inflammatory disorders of the bowel, and after operations for hæmorrhoids and fistula. It is fitted with inlet and outlet pipes for continuous irrigation—a mode of treatment I adopt after all rectal and perineal operations at the Royal Portsmouth Hospital, and I hope to describe its utility in these cases on a future occasion.

Whenever internal piles come down during defæcation, they must always be carefully washed and returned. In prolapsus ani the protrusion should also be carefully pushed back directly the stool has escaped. Many of my patients, labouring under aggravated troubles of this sort, have experienced much relief by using for a few weeks a bed-pan in the horizontal position. At all times the inconveniences attending the act of defæcation may be alleviated by introducing into the bowel a lubricating agent to prevent undue straining, and to facilitate the

[1] The purified fat obtained from sheep's wool is the best basis for all ointments intended for soothing and protecting purposes.

escape of the motion, and for this purpose the antiseptic compound I have mentioned is admirably adapted. The anus should then be carefully washed, and a little stimulating ointment put into the bowel, to check excessive secretion, and to rouse the mucous follicles to more healthy activity. I often employ a remedy containing a little oxide or subchloride of mercury and a few grains of iodoform. If pruritus ani is troublesome, cocaine may also be added with much advantage.

It is necessary here to refer to a matter which generally receives too little attention. Patients should always be instructed as to the right way of applying local applications. It is of great importance that these are distributed upon the mucous surface of the bowel well within the sphincter, and the only way of obtaining this result is by the use of an ointment introducer. The simple instrument I have designed for this purpose is represented in the engraving (Fig. 1). It consists of a very smooth anal tube, a cylindrical receptacle for the ointment, and a vulcanite piston. The ointment is projected through the perforation in the anal tube by simply compressing the piston with the finger. The injector is very readily charged, and is especially adapted for self-application. The rectal injector (Fig. 2) is intended for the use of fluid remedies,

Fig. 1.

Fig. 2.

and is capable of holding three drachms. For the introduction of larger doses the anal tube can be used with a second hand-ball.

Hæmorrhage is often a very prominent symptom in many of the common disorders of the rectum. The quantity of the discharge varies a great deal in different cases. At all times the amount of blood lost at each evacuation must be carefully ascertained. Sometimes the fæces are only smeared with spots and streaks of blood, while at other times the loss is very considerable and alarming.

Whenever free bleeding has suddenly occurred, or the drain has continued for a long period unchecked, the case is not one for mere palliative treatment, but ought to pass without delay into the hands of the surgeon.

In many cases, however, of moderate severity, the daily use of local remedies will be followed by great benefit. The same diligent attention to cleanliness after an evacuation must be practised, and then an ointment containing the persulphate of iron should be carefully applied to the diseased surface. The fluid extract of witch hazel is also a very efficacious remedy. When a very powerful hæmostatic is required, the persulphate may be added to the hazeline with great advantage. I generally order two drachms of this solution, diluted with a little water, to be used regularly for two or three weeks. For all cases of hæmorrhage, rest in the horizontal position after defæcation is extremely desirable, as it tends to relieve the local congestion, and to promote the astringent action of the remedy.

One word respecting the value of anodyne applications. The distressing pain which attends the evacuation of the bowels in some diseases, and continues for hours after, often demands local palliative treatment. Many cases of pain and spasm of the orifice are greatly relieved by the topical use of cocaine; but, after many trials, I found a combination of morphine and cocaine more generally useful. The application of this compound sedative often acts like a charm, and quickly gives relief. The suffering caused by fissure of the anus and ulceration within the sphincter is rendered bearable by this remedy, and in recent cases I have sometimes found its use, combined with digital dilatation, rapidly followed by permanent cure, without any other surgical interference. It is invaluable in the treatment of stricture of the rectum, and it should be introduced into the bowel ten minutes before the use of the dilator. In chronic ulceration and malignant disease it can be freely employed as a palliative remedy; and, in fact, in all cases in which pain and hyperæsthesia are prominent symptoms.

MEDICINE IN AUSTRALIA.[1]

By T. N. Fitzgerald,

Fellow of the Royal College of Surgeons, Ireland; President of the Congress.

When, sixteen months ago, at the first medical congress ever held in the Australiasian colonies, I was chosen president-elect of the next similar gathering, I was very proud to have obtained such an honour. I received with feelings of profound gratitude the expression of confidence and regard that my fellow-workers in the noblest of all vocations were so good as to convey to me. And now as I stand before you, who have come hither from every part of Australasia, to take counsel together on matters of grave import, I feel that I have reached the crowning point of my ambition; for I need hardly say that although material success is very properly an object we may all laudably strive to win, if only we strive fairly and honourably, a still higher prize is that which is conveyed in the willing trust of a whole brotherhood. I wish, therefore, here to declare how deeply sensible I am of the honour of which I was then made the recipient, and how proud I am to occupy the place that now I fill. Let me, however, sincerely assure you that I feel conscious of considerable diffidence in having so closely to follow the late president, whose eloquent address in Adelaide won from us such enthusiastic and well-merited recognition.

And now let me offer you all a cordial welcome to Melbourne, which some of you, I dare say, behold for the first time. Our city has been called "Marvellous Melbourne," and no doubt for some reasons it deserves the title. It is very far from perfect, as we who have lived in it so long well know. To it, then, such as it is, I bid you welcome. We will endeavour to make your stay in it as agreeable as we can, so that when you leave us you may carry away not unpleasant reminiscences of your visit.

Before proceeding further, permit me to offer a few words of explanation. You are no doubt aware, before we left Adelaide, it was agreed that the congress should be convened in 1890, and this resolution would doubtless have been adhered to had not the political authorities of the day suddenly decided to hold the Centennial Exhibition

[1] Presidential Address delivered at the Second International Medical Congress, Melbourne, January, 1889.

and invite all nations. When the commissioners were debating their preliminaries a proposition was started that this would be a very favourable opportunity for holding the next session of the congress. The suggestion at first encountered serious opposition from many who are generally foremost in support of any movement that tends to the advance of medicine, and whose opinions deserved most attentive consideration. The change comtemplated was no doubt an important one, more especially as it involved a direct departure from the resolution agreed upon in Adelaide; but it was urged that, although a year's time was a very short interval between the two meetings, and allowed but a brief space to collect fresh facts and arrange material, yet the chance was too opportune to be missed. At another time the means of travelling from distant parts would not be so easy, and assistance from other sources might not be so readily attainable. Consequently it was determined, on a full vote of the profession, to alter the Adelaide programme, and to convene our gathering this year. The date being fixed, those who had opposed the alteration the most strongly very generously consented to act with the larger section, so that we have since worked together in perfect harmony in making the preliminary arrangements. I am delighted to say that the fear expressed by the opponents to the change, that the time would be too short to collect sufficient material, has not been justified by the results, and that we have experienced from all quarters a most gratifying readiness to co-operate with us in making the congress an unqualified success.

It has been asked, what are the especial advantages to be looked for from an Australian medical congress? What practical good is likely to come from the gathering together of medical men in the southern lands? Are there, it is demanded, any diseases peculiar to Australia, or affections which have not been investigated exhaustively by the highest authorities in Europe? Do the conditions of climate and the social habits of the people modify diseases? Or do certain affections, which are common to all latitudes, assume here particular characters that differentiate them from the aspect they present under other geographical circumstances?

I do not forget that on the other side of the world, and especially in those large centres of human life where the perils of existence and the factors of disease are so many and so constant, the finest intellects are continually engaged investigating in every branch and every branchlet of the compound science of medicine. They have abundant means, elaborate appliances, the fullest opportunity, and uninterrupted leisure at their command, to work out the problems which continually are spread before them. The microscope enables them to make additions every day to the sum of that division of the medical sciences which half a century ago, or even less, may said to have no existence. Histology is thus always revealing to them, and through them to the whole medical world, something new. The chemist, in like manner, is for ever throwing light upon etiology, pathology, and, especially in its larger significance, therapeutics. There are very many highly accomplished men content in their enthusiasm to spend the spring-time and early summer of their lives in the exhausting work of hospital duty; happy and well enough rewarded in their own esteem if they but do now and then, amid thousands of routine cases they have to treat, light upon some new clinical fact, or discover some hitherto unrecognised action of a drug. Surely, asks the pessimist querist, your local medical societies suffice for the report of unusual cases, and the exhibition of anatomical peculiarities or rare distortions; why then, with puny strength, endeavour to emulate the mighty efforts of the northern hemisphere, having in remembrance that some of their endeavours have not been crowned with perfect success?

We do not, we cannot hope to bear comparison with the great medical gatherings of the congresses or associations in Europe. But with all becoming humility, and with the admission that we cannot hope for some years successfully to rival our brethren in the healing craft in the old world, I have yet to say that we have here 2000 medical men, educated and trained in the same way, and qualified up to the same limits, as are those at home. We have amongst us representatives of nearly every medical school or college in Europe, who have opportunities of studying and treating disease and of maturing their knowledge, both in private and in hospital practice. Then again, as we all well know, in many medical and surgical affections, the practice adopted by some of the leading men in the different colonies is decidedly at variance (whether rightly or wrongly) with the views held by home authorities. Surely, therefore, we are able to add something to the sum of that knowledge which we have as a kind of joint stock, and to the enlargement of which it should be both our duty and pleasure to contribute.

To reply further, it should be remembered that though the habits and conditions under which we live bear a social similitude, yet they are by no means identical with those existing in Europe. In the older civilisations and in America, we see the working population of the cities crowded together in a manner utterly unknown to us. The facts lately published by the Special Sanitary Commissioners of the *Lancet*, on the sweating system among tailors in Liverpool and Manchester, must be an incomprehensible revelation to the native-born of these colonies. In the rural districts of the old country, the labourers are ill and insufficiently fed, ill-clothed, over-worked, and everywhere subjected to the extremes of cold or heat in their seasons. The wealthy, for the most part, especially the females, are fashion-worshippers, self-indulgent, and almost entirely unemployed, the more active alone finding vent for their energies in eleemosynary efforts.

With us, on the other hand, the cities are widespread (too much so if anything), each man, even to the poorest, lives in his own house, animal food is plentiful and cheap, the hours of labour are short, and summer and winter are much the same, except that in their seasons occasionally the hot days are hotter and the cold days are colder. Such weather as is implied by the terms zero, blizzard, continuous rain, ice storms, etc., we are acquainted with only through newspaper description. On certain days it is true the heat is apt to be oppressive, specially to the inactive, and trying to the aged and sick, yet it can never be said to be unbearable, or inimical to life. Then again, the difficulty and often impossibility of ensuring constant domestic service, compel even the most opulent of this community to do for themselves what they would be glad to pay others to do for them, and thus in the performance of work, our gentlewomen procure for themselves an amount of bodily exercise, which, although unsought and sometimes unwelcome, is a distinct benefit to them, and there can be no question that it saves them from many ills to which they would otherwise be subjected. Thus, then, in this continent we find men of all classes living under the most favourable circumstances. Climate nearly all that can be

wished for, healthy inheritance, both mentally and physically, ample space for every one, and well requited industry prevailing everywhere.

Surely with these happy surroundings, which exist, as far as I am aware, to such an extent in no other place, we have a spacious field, especially our own property, for investigating disease as it occurs uninfluenced by the many causes which excite and maintain it at home. For instance, we have long been taught, rightly or wrongly, that scrofula and tubercle are affected by squalor and dirt; that phthisis is favoured by close vitiated atmosphere and cold night air. These causes are present but to a slight extent with us, yet occasionally we find scrofulous impregnations excessively virulent; while phthisis is as common with us as it in England, and decidedly more so than in Canada and Scotland.

Again, here in this land, certain acquired constitutional diseases in the tertiary ulcerative forms, are comparatively mild affections, and seldom present that grave character which is such a continual source of anxiety to the European practitioner. As a corollary to the limited intensity of such affections, we would expect to find skin diseases rare and mild in character. Is this the case? We are a busy people, yet melancholia is a common form of insanity to be met with in our asylums. Then, again, do we enjoy an immunity from the nervous diseases so frequently to be met with in the great manufacturing and mercantile centres of Great Britain? And if we do not, what is the explanation? It is not difficult to discover, therefore, that the field for observation is here very wide, and that in whatever direction of special knowledge we may look there is an abundance of matter to interest and occupy us, without at all travelling over trodden paths, or turning over ground which has yielded up all its nutrient elements to the cultivator.

There are a number of similar questions we can ask ourselves, and our peculiarly happy circumstances will perhaps allow us, by a process of elimination, to throw a light on obscurities, and to regard causes from a point of view from which, without these advantages, they cannot be seen by the profession at home. So, too, should we ask ourselves, cannot advantage be taken of our almost unlimited space to bring under control such distressing social maladies as habitual drunkenness? Then, again, is not this the opportunity to come to some agreement as to where a suitable mountain residence can be found for the delicate and consumptive? Whether a better treatment may not be advised in counselling protracted change—summering in New Zealand or Tasmania, wintering in Queensland, and spending the intermediate time in one of the other colonies?—for we have all climates with us.

To arrive at any definite conclusion on these and many other matters, a consensus of opinion is required, and this can only be obtained by such a gathering of the profession as I see before me now. If our environments are healthful, and certainly they should be so, the young manhood of this country, who, for the past few years only, has become an influence in the councils, should present a type of the highest class. His birth-right, the political freedom which has been handed down by his fathers, his inheritance, the home life, the decorum and gravity of a race bred under a cold uncongenial sun, untrammelled educational establishments at his very door, no class distinction to sneer him down, and every opportunity to gratify any inclination either in the playground, the workshop, or study, the Australian native should stand forth as the creature best able on earth to resist disease, and the most willing to listen to wholesome advise on sanitation. His love of outdoor sports, engendered by the easy hours of labour and the many open reserves, saves him from the several temptations which surround life at the time of its puberal development, whilst the constant sunshine, the frequently recurring holidays, and variety of amusements relieve his toil from the chilling monotony that in other countries is the parent of habitual intemperance. Why then, in such an apparent paradise, peopled by those who ought to be Hercules and Apollos, are our death rates so high? This is a question that, doubtless, the congress will inquire into, and its deliberations will, I trust, throw some light upon those vexed matters of drainage, ventilation, and other items that so intimately affect the sweetness and healthfulness of life.

I wish, however, to draw attention to one or two points which, though perhaps well known to the profession, are not generally recognised by the public at large. In all English-speaking communities the mortality bills are swelled principally by three affections—alcoholic intemperance, tubercular deposits, and typhoid fever—scourges in the main preventible; but the remedies for which, either from the expense, or from other causes, we will not boldly and manfully face.

First then, with regard to drink. You all know how inimical to treatment its effects are, and how great is the misery it occasions. I have no wish to read you a teetotal lecture; there is, however, one peculiarity which stands out rather prominently, and which I think should have weight with us all, when, as medical men, we are called upon to prescribe spirits as a drug; and that is the fact that alcohol is much more potent with us than it is at home. If we turn to the statistics that Mr. Hayter annually furnishes to the Government of Victoria, we find that the deaths set down to drink are numerous compared with those of even the most intemperate countries, and such a calculation would naturally lead to the assumption that we Australians are an extremely drunken people. I do not desire to go out of my way to find excuses for much excess in this particular, nor would it be proper for me to say that there is no drunkenness in Australia, but I assert with the strongest emphasis that habitual drunkenness is an exception with us. Visitors from abroad, who have been to any of our great gathering at military displays and racing carnivals, or who have seen the crowded attendances at athletic meetings in any of the colonies, must have noticed the absence of drunkenness and rowdyism. What really is the case is that alcohol, in whatever form it may be taken, is not suited to the climate or the conditions of the people, so that hepatic and renal affections are sooner and more frequently engendered by its use than they would be under the same circumstances in a colder country.

Looking at the habits of European populations, however, I cannot but regard it as a slander upon our manhood to charge them with systematic drunkenness. A great number of our native born youths are total abstainers from birth, and, while not forgetting the intemperate opinions sometimes expressed by temperance advocates, I must admit that temperance societies have worked a good deal of useful reform. As a food in the low delirium of fever, and as a means of preventing waste of tissue in erysipelas and kindred diseases, and for the aged, alcohol is doubtless essential, and of great service. Yet the death-rate ought, I think, to teach us the necessity of care in the use of intoxicating liquor, and that, as medical men, we should be very cautious, far more so than our brethren have need

to be in colder climates. What we have to regard is the great probability of its continued and over-moderate use being prolonged when the necessity for its employment has ceased, and of its setting up local congestions, which, in time, destroy the functions of the organs they effect.

Of phthisis and typhoid fever I have already said that the former appears to be nearly as common in Australasian as in English towns; and typhoid, both in urban and rural districts, is nearly of twice as frequent occurrence. I think it offers occasion for the gravest consideration to discover how, in a country so richly endowed, and with a climate so genial, we should yet be afflicted to so terrible an extent with two diseases of parasitic origin, both of which, pathologists assure us, are eradicable. It is curious to notice how the etiology of phthisis has varied among physicians from time to time. In my early days it was impressed upon us that consumption chiefly arose from defective ventilation, and the inhalation of irritant particles. Then came the catarrhal or pneumatic organs—neglected colds and so forth—and now we find that neither nor all of these reasons will suffice to account for the large bills of mortality from phthisis in this land. In my opinion, next to its hereditary inception, the greater part of phthisis will be found to be associated with defective drainage, and this, I believe will be proved by bacteriology. I cannot but think, therefore, that it will always be endemic with us until we devise some proper and complete method of carryiug off our sewage and fluid house refuse.

Typhoid fever is with us a true *opprobrium medicorum*. It is with us, of us, among us, upon us. It is a spectre we apparently cannot exorcise. It is truly "the pestilence that walketh in darkness, and the destruction that wasteth at noonday." It is at once a terror and a reproach. It defies legislation and administration, it laughs at boards of health, and triumphs ruthlessly and always. Are we never to cope with this terrible affection? As far as Melbourne is concerned, we hope much from the commission which is now holding its meetings; and we trust that whatever scheme is decided upon, it will be adopted without the long delay that generally follows the decisions of such bodies. But in the meantime, the same things go on. Streets are marked out, and houses are built without the semblage of drainage, Then the warm weather comes, and fever stalks each year more greedily and viciously than before. No doubt the section constituted to discuss these matters relating to hygiene and public health will indicate what steps modern sanitation should take towards the suppression of this conspicious evil. The views of medical men and health officers are always valuable when they take some practical step, especially on such a subject as public health. On such matters they alone, from their educational training, are capable of expressing opinions worth listening to. I sincerely trust our health boards will derive information from the deliberations of the section of hygiene.

All branches of our profession seem steadily to advance. Annually some new surgical measures are contrived, some new drugs are introduced, some disorders discriminated. What future is there for sanitation? Sanitation, unlike other divisions of our art, must go hand in hand with the educational progress and mental improvement of the people. Without the schoolmaster, all efforts we could make must inevitably prove futile. An intelligent conception of its purposes by the authorities, both parliamentary and local, is absolutely necessary. It is here that I hope much may result from such a gathering as this congress, for in all matters that relate to medical and sanitary requirements it seems to be nearly an invariable rule for legislative enactments to be considerably in arrears. With borough and shire authorities, I believe these bodies do, in the main, the best their lights permit them, but the insanitary conditions of their respective localities are attributable, I conceive, to either a want of information, or a reluctance to exercise their powers. Because diphtheria happens to be absent for a time from their district, they fail to see danger in a cesspit, or the necessity of milk inspection, and so forth. Doubtless the advanced education the young are receiving, in at least the better class of schools, the instruction in the elements of physiology and the general principles of hygiene, will in time have its effect on our future statesmen and councillors. And in this direction I think much benefit might accrue from the appointment of a few thoroughly trained and carefully chosen sanitary instructors, whose duty it should be to travel from town to town, and even from house to house, with the object of teaching the principles and the advantages of health laws, and the consequences of a disregard of them, for it is certain that the value of cleanliness cannot be properly understood until the dangers of filth are comprehended.

I should like while on this subject to say something in strong praise of the hygienic arrangements that have been carried out in Adelaide. The method of drainage appears to be as nearly perfect as it can well be, and as there is a large model of the system in the South Australian Court of the Exhibition, it would be well that everyone interested in this subject should see it. If it be possible to adopt in this much larger city the same system, I am prepared to say that the death-rates would be lowered to an extent now hardly dreamed of. Nor is the incidental advantage in connection with this system of the disposal of the sewage to be lost sight of. The Adelaide sewage farm is a very joy of scientific agriculture. In Sydney they are commencing with earnestness to drain their busy city; and although the underground drainage of Melbourne is at present little more than rudimentry, we have at last made a beginning.

But what is more encouraging, and prognosticates well for the generation that is to follow us, is the lusty outdoor life, and the sturdy games the Australian so dearly loves. Amongst those who ever have seriously revolved the subject in their minds, some doubt must have arisen whether the youth of these great colonies would walk in the steps of their parents, or influenced by a hotter sun, follow in the wake of their American kinsmen, and forsake the green sward for light amusements, ease, and luxury. I rejoice to say that this question is entirely set at rest; the Australian's prowess on the river and the cricket-field has settled that matter, and he promises, as far as physical development goes, to even surpass his fathers. It is rather extraordinary that the out-door life and national games of the mother country should have taken such a hold on the young folk of Australasia, for I believe in no other part of the world have the sons of the Anglo-Saxon or Celtic emigrants done the same. Certainly, in America or South Africa, neither cricket nor football is generally played. Now, this love of these manly games must have an influence for good on the manhood of this country. Personally, I have no sympathy with those who would decry these athletic exercises, either because at times they

may be carried out too roughly, or sometimes are accompanied by some degree of danger. The very roughness of football is an element of good. It develops courage and good temper; one hears too much nowadays about gentleness and the velvet hand. We require a little fibre, which these games tend to impart. When I look at the footballer ready for action, I cannot help admiring his muscular frame, and sympathising with him in the pride he takes in his sturdy limbs, his form, and activity. Contrast him with the boy one meets with on the Continent, parading through the streets. Which is the more likely to grow up a self-reliant, useful citizen, the footballer or the young gentleman who spins his tops and bowls his hoops in gravelled enclosures? Depend upon it, these games are important factors in the formation of the moral tone of this country. We should encourage them to the best of our powers, and endeavour to allay the fears of timid over-anxious parents. If a few limbs are broken annually, and even now and then unfortunately a death occurs, it would be better that four times the number of casualties should be told, than that our boys should grow up hypochondriacal and dyspeptic.

Looking round this assemblage of representatives of the great guild of medicine, drawn here from every province of Australasia, I cannot deny myself the pleasure of thinking that we are all students, still engaged in the work upon which we entered, some of us, many years ago. We have had our ambitions, our difficulties, our trials, our disappointments, and now and then our successes. We have been engaged in the hard business of living; we have had to contend with opposition on many occasions, and sometimes we have had good reason to believe we were not too fairly dealt with. However, I am sure it has been the consolation of all of us to feel, that in the acquirement of the knowledge necessary for the exercise of our craft, we command a source of enjoyment that nothing in the way of fret or ill or mere professional failure could take from us. We have thus all added something to the common store of medical knowledge. We have in this way experienced a delight compared with which the greatest material success holds only subordinate place. Like another God-like attribute, the *ars medendi* "blessed him that gives and him that takes." It is a delight to make discovery in our science; but I am sure it is a delight still greater to know that the discovery may be of service to our professional brethren in relieving suffering humanity. It is thus a privilege to thank God for, that our domain of discovery can never be exhausted, and that no matter how great may be the researches of others, there is still left room for us to go on exploring. It is the very glory of medicine that it is not finite. It has been brought against it as a reproach that both its principles and its practice are always undergoing changes. I reply, with a feeling of triumph, that these changes are the very evidences of our progress. If we have a motive at all, it is "Onward." It is not our despair, but our boast, that medicine is not an exact science. We are not content with what we have done, but we look forward to the greater, the better, and the higher doing. "Still achieving, still pursuing," we "learn to labour," and if we "wait" at all it is not in the dull apathy of contentment at what has been done, but in the belief that the "Greatest is behind." It is with this feeling, this hope, this ever constant and unswerving faith that I regard the coming together of my brethren on this the opening day of the second session of the Medical Congress of Australasia.

DEAFNESS AND DEAFMUTISM, IN RELATION TO SPEAKING AND LIP-READING.[1]

By James Erskine, M.A., M.B.,

Surgeon to the Glasgow Ear Institution.

The term "deafness," as commonly used, denotes any impairment of hearing, and gives no definite indication of the degree of the defect. By "dulness of hearing," is generally indicated a comparatively slight degree of impairment. The same term is often used as an euphemism when the patient is inclined to take too favourable notice of his defective hearing, and is therefore apt to delude others as well as himself. A correct estimate of the auditory defect in all cases can only be formed from careful examination by means of the usual tests—namely, (1) the voice, (2) the tuning fork, (3) the watch, (4) Galton's whistle, (5) the acoumeter, (6) the artificial drum, (7) the hearing tube, and (8) the audiphone. The three last named are also employed as aids to hearing. The artificial drum in appropriate cases often increases the hearing power very greatly, the improvement quite astonishing the surgeon as well as the patient. The various forms of artificial tympanic membranes should be tried, because sometimes one is found that suits the particular condition of the middle ear better, and produces much more improvement of the hearing than others. Patients and the public should be warned against the deception that the "ear-drums," as advertised by quacks, can be used with benefit in any case. The hearing-tube or ear trumpet enables some patients to hear the voice, and distinguish the words spoken into it. The audiphone is useful in the same manner, but is not so convenient. Such aids to hearing as the hearing-tube and audiphone are repulsive to most patients, and only in a small proportion of cases are they found to be practically useful. Young people especially do not readily avail themselves of the benefit they may yield.

If the patient cannot hear sounds either by air-conduction or bone-conduction, he is pronounced totally deaf. In many cases the loss of hearing may be by no means absolute, although the degree of hearing power that is retained may be of no practical value. The patient may be able to hear the sound produced by a vibrating tuning-fork when it is placed on the bone behind the ear, or on the other bones of the head. He may even be able to hear the sound of a loud clear voice when delivered close to his ear, but be unable to distinguish the words. Such a person is practically deaf. Any degree of defective hearing amounting to inability to distinguish words spoken into the ear in a loud clear voice may be termed deafness. The term dulness of hearing may be used to denote any degree of impaired hearing co-existent with the ability to hear words intelligibly when distinctly pronounced near the ear.

In the case of a young child the degree of deafness appears greater than it really may actually be, because the child does not make such an earnest endeavour to hear as the adult deaf person. It is a very serious matter for a young child, say about two or three years of age, to lose the ability to hear even the voice as used in general conversation. Such a child soon gives up listening altogether, and in consequence ceases to speak because it cannot hear others speaking. In very young children this result may follow a comparatively slight deficiency of hearing power.

[1] Read before the Glasgow Southern Medical Society, February 21st, 1889.

The tendency to dumbness as a result of the occurrence of partial or total loss of hearing in the case of a child depends on the age of the child at the time, and the degree of deafness acquired. It may be laid down as a general rule that if a child becomes deaf before the age of four years, dumbness almost always follows. The speech is very often lost even if the deafness is acquired between the age of four and seven. The younger the child the smaller is the degree of defective hearing that will produce dumbness. But in any case the speech of the child may be retained if means to practise it be taken by the guardians or parents, being alive to the danger of losing it altogether. In the case of an intelligent child who has learned to read it is quite possible by making it read aloud for a certain time every day, and by teaching lip reading, to retain known words, and add others to its vocabulary. There must be no delay, however, in attending to the tuition of such a child after the loss of hearing. By neglect, such cases soon become almost as intractable as those of the congenitally deaf.

There can be no question as to the importance of hearing words by the child in its very earliest years. Learning to speak is an imitative process. Even in its first year the child's vocabulary is mainly composed of more or less successful attempts at imitation of the words of the language of the mother, the nurse, and the people by whom it is surrounded. It also imitates the sounds of natural objects, and uses them as signs of the objects. By the loss of hearing, the young child is therefore deprived of the use of these natural sounds, and also of spoken words which are ready-made instruments for defining and expressing thoughts. When a child does not hear the words used to denote the objects by which it is surrounded, it soon gives up using the few words it has learned. This result occurs because the words are as nothing to the child when it cannot hear them. The relation of the thought to the word in the case of children is by no means an abstract one. The word is merely a label put upon the article by which it is known. The words which a child has learned as the names of things are only applied by an objective experience. Some appeal must be made to the child by the object of thought through the senses before it will apply the name. It therefore does not use words abstractly, and so forgets them readily. The surroundings supply the young child almost entirely with thoughts. Place it in new surroundings, and it will have little left to relate it to former circumstances. The use of words is essential to the mental development of the child. The more words it uses the better will it be enabled to think.

The number of cases of congenital deafness is small in proportion to the number of cases of acquired deafness. The record at the Glasgow Ear Institution, made during the last eighteen months, and comprising sixteen hundred individual patients' cases, contained fifty-eight cases of deafness as already defined. Only eighteen of these were cases of deafmutism, or deafness and dumbness. The following were the ages of these patients when they were brought to the Institution—namely, seven under three years; four between three and four years; three between four and five years; one between five and six years; one between six and seven years; one between seven and eight years, and one aged thirteen. Only six of the eighteen were proved to be deaf since birth. Of the other twelve, five had suffered from meningitis; two from destructive purulent inflammation of the ears; two from convulsive fits during whooping-cough and teething; one from hereditary syphilis; one from injury to the head, and one was reported to have been deaf after a fright. All these children were regarded as deaf and dumb for longer or shorter periods before they were presented for the purpose of obtaining a medical opinion on their aural defect, and advice in reference to their education.

The faculty of speech had been retained in forty cases out of the total fifty-eight. These forty patients had lost their hearing after they had reached the age of ten years. Between the ages of ten and fifteen there were five cases recorded; between fifteen and twenty, six; between twenty and twenty-five, six; between twenty-five and thirty, five; between thirty and thirty-five, four; between thirty-five and forty, four; between forty and fifty, five; between fifty and sixty, two; between sixty and seventy, two; above seventy, one. Chronic purulent inflammation in twelve cases had destroyed the middle ear and adjacent structures. It is noteworthy that such a large proportion of the cases resulted from neglect of what is commonly called "running ears." Some of the patients stated that their ears had been discharging matter as long as they remembered without any attempt at appropriate treatment. One of those twelve cases was associated with hereditary, and another with acquired syphilis. In eleven cases the symptoms and appearances in the middle ear were referable to chronic dry catarrh, the deafness having been progressive during a long period. In one case the patient described the symptoms that had preceded the occurrence of complete deafness as having set in during severe seasickness. In five cases there were indications, and the history of hereditary syphilis, and in one of acquired syphilis. In four, Menières complex of symptoms were more or less marked as preceding the extreme degree of deafness. Cerebral symptoms were reported in other four cases. Sunstroke produced loss of hearing in one case, and injury to the head preceded it in another. In one case no definite history of appreciable symptoms could be obtained.

The percentage of deaf mutes in the total number of the 1,600 patients is 1.125, and the percentage of deaf, but speaking, patients is 2.5. Taking deaf patients under the age of thirty-five as those likely still to be concerned about their education, we find that the number amounted to twenty-six in 1,600, that is 1.625 per cent., or rather more than the percentage of deaf mutes. The ages of those deaf people given in the statistics are, of course, in advance of the ages at which they became deaf, many having suffered from greatly impaired hearing for months or years previously. It is perhaps unnecessary to state that all the cases under review are those of incurable deafness. It should also be pointed out that the proportion of cases of deafness and deafmutism, as shown by the statistics, is necessarily large in relation to the total number of 1,600 cases, as these were all cases of patients complaining of disease or injury of the ear in all their various forms and degrees.

From observation of the records of the ear institutions in this country I have found that the proportion of deafmutes to the total number of patients is about twelve in 1,000. Possibly some patients may be included in the number who were deaf, and not absolutely mute. The proportion of deaf-mute patients at the Glasgow Ear Institution, it may be again noted, was 1.125 per cent., or 11.25 per thousand.

The proportion of deaf-mutes to the hearing population is, of course, much smaller than what is found in relation

to the number of cases of diseases of the ear. According to the last census there were in Scotland 573 deaf-mutes in every million of inhabitants, that is, one in every 1,744, or 0.57 per 1,000, or 5.70 per 10,000. The proportion of deaf-mutes to the hearing population of the world is said to be about seven per 10,000. The number is highest in Switzerland—namely, 24.5 per 10,000; and the lowest in Holland—namely, 3.35 per 10,000.

Deafmutism is most common in hilly countries, the inhabitants of which are necessarily given to intermarrying with near blood relations. In some parts of Scotland, especially in the islands from which there is limited communication with the mainland, the number of deaf and dumb is said to be large. In the village of Lamlash, in the island of Arran, the number of deaf-mutes is reported as six in a population of about a thousand. Deafmutism is more prevalent in certain religious persuasions than in others. It is commonest among Jews on account of their close intermarriage. The proportion is smallest among Catholics, to whom such marriage is forbidden. The number of deaf-mutes in China is very small, as consanguineous marriage is positively forbidden by law. There can be little doubt that consanguinity in marriage is an important factor in producing congenital deafmutism. Heredity also plays a great part in the transmission of deafmutism. The most remarkable case I have seen was brought to me about five years ago. The boy was five years of age at the time. The following members of the family to which he belonged were deaf and dumb—namely, his father and mother, one paternal and two maternal aunts, his paternal grandmother's two full cousins, as well as her second cousin. Direct transmission of deafness from parents to child is very rare, according to Dr. Hartmann, of Berlin, a leading authority on the subject. He shows that indirect transmission is more frequent, children often inheriting a defective constitution, which must also be supposed to account for the occurrence of congenital deafness in a family without apparent hereditary tendency. Dr. Kramer describes one family in which six sons were born deaf, and five daughters with perfect senses, while the parents were both healthy. Professor Politzer reports that he saw in one family in which there existed no hereditary disposition, four deaf mutes out of ten brothers and sisters.

Professor Graham Bell, in a report very recently presented to the United States Census Commission, shows that the deaf-mute population is now nearly four times what it was in the year 1850, the total population having only somewhat more than doubled in that period. He traces the transmission of deafmutism through four generations. The percentage of intermarriage, he states, has continuously increased, till now not less than 90 per cent. of all deaf-mutes who marry take partners who are themselves deaf and dumb. At the date of the last census (1880) he finds that one person in every 1,480 of the general population was deaf and dumb, and one in every sixty-four of the deaf-mute population was a child of deaf-mute parents. One person in every 2,756 of the general population was deaf from birth, and one person in every thirty-eight of the congenitally deaf was a child of deaf-mute parents. Professor Bell points out that by the laws of heredity, if these deaf children marry congenitally deaf husbands or wives, an increased proportion of deaf offspring will appear in the next generation. The continuous intermarriage of congenital deaf-mutes from generation to generation will ultimately result, he declares, in the formation of a deaf variety of the human race in America, in which all or most of the children will be born deaf.

Such facts as these should awaken the people of this country to a sense of their duty of caring for what is somewhat coldly entitled one of the "defective" or "abnormal" classes of society. The Education Act of 1872 declares it to be desirable "that the means of procuring efficient education for their children may be furnished and made available to the whole people of Scotland;" and Section 69 declares it to be "the duty of every parent to provide elementary education in reading, writing, and arithmetic for his children between five and thirteen years of age." Why should deaf children, or any other abnormal class, be excluded from sharing in the benefits of the universal boon of a common education?

It is becoming too late in the day to discuss the comparative merits of the oral method of instructing the deaf as compared with the finger or sign system. As far back as the seventh century we find an instance recorded of teaching the deaf and dumb to speak. The Venerable Bede describes how the Archbishop of York, St. John of Beverley, taught a dumb lad by the oral method. Towards the end of the fifteenth century Rudolph Agricola, of Heidelberg, wrote a book entitled, "De Inventione Dialectica," in which he tells of an educated deaf-mute who had been taught by him to speak. In the following century Pedro de Ponce, a monk in a Benedictine monastery in Spain, taught speech to deaf-mutes. He really occupies the earliest important position as a teacher of the deaf and dumb. It is notable that the first successful teachers, both of the oral and sign methods, were Benedictine monks, for the founder of the digital system, the Abbé de l'Epée, belonged to the same order. As promoters of the oral system, there followed after De Ponce, Dr. John Bulwer, a physician, the cheirosopher of England, and Dr. John Wallis, professor of mathematics at Oxford, who both lived in the later half of the seventeenth century. Dr. Bulwer published a work entitled, "Philocophus, or the Deaf Man's Friend." Professor Wallis showed to the Royal Society a deaf-mute pupil of his own, who was able to speak and read the lips. John Conrad Amman published a book in 1692 called "Surdus Loquens" (the speaking deaf). He was the most eminent instructor of the deaf in Holland, and established the oral system on a definite basis. It was not till the middle of the eighteenth century that the cause of the education of the deaf and dumb was taken up in France by Pereira at Bordeaux, who became a teacher of the oral system, but he made a secret of his method, and would only give his services to the rich in return for high fees. The first institution for teaching the deaf in France was founded at Paris by the Abbé de l'Epée, who taught entirely by the digital or sign system, which is, therefore, called the French system. The oral method of articulation and lip reading was first systematically taught by Samuel Heinicke, who started an institution for the deaf and dumb at Leipsic in the year 1778. Hence this system is called the German or oral method. Heinicke entirely discarded the fingers and signs, and met with much success. The first school for the education of the deaf and dumb in Great Britain was established by Thomas Braidwood in Edinburgh in the year 1760. We have still its local name of "Dumbiedykes," preserved in Sir Walter Scott's "Heart of Midlothian." In his teaching Braidwood adopted the oral method. He seems to have been very successful, and to have attained wide celebrity. Dr.

Samuel Johnson paid a visit to his school, and expressed himself highly pleased with his mode of instruction. The history of the education of the deaf and dumb shows that from the earliest times, they were trained to speak, and also to read the lips. We need only refer to the modern institutions and schools in this country and throughout the world, successfully teaching by the oral method. Even in France, the very birthplace of the sign system, the oral method is fast gaining ground. There are about fifty institutions in Great Britain and Ireland devoted to the education of the deaf and dumb by the two methods, and by a combination of them. The International Congress on the Education of the Deaf, held at Milan in 1880, declared unreservedly in favour of the pure oral system. The best authorities on the subject are of the same opinion. The combined system has met with very little favour, as the two methods are mutually destructive.

What is urgently called for is provision for the education of our deaf children in our public schools by the oral system. The School Boards of London, Leeds, and Sheffield, made arrangements, a few years ago, for such instruction of those unfortunate children. In Scotland, the School Boards of Dundee, Greenock, and Govan, have done the same. There is no good reason why the deaf should be allowed to become dumb, and, therefore, suffer mental, social, and other disadvantages. The only thing of which a deaf-mute is deprived is the sense of hearing. He is in full possession of the organs of articulation. The time was when it was held that these organs were at fault, and not the ear. This was the case till the end of the sixteenth century. For a long time the deaf and dumb had been regarded very much as imbeciles, but when it was discovered they were perfectly rational, all manner of operations were performed on various parts of the organs of speech, and it is fearful to think of the tortures which this afflicted class had to endure by reason of this error. Valles, the surgeon to Philip II. of Spain, who lived about the end of the sixteenth century, was among the first who showed that the organ of hearing was at fault, and not the organ of speech—that dumbness resulted from deafness.

Parents and guardians have a right to demand for their deaf children a common education in the ordinary public schools. It is a terrible hardship for parents to educate their deaf children as they would desire, by reason of the expense. It is the duty of School Boards to provide the means of education for deaf children along with hearing children. The Education Acts do not specially make provision for such teaching, but the School Boards have the power to teach them if they are inclined to do so. Surely the small matter of a little extra expense for providing specially trained teachers for the work ought not to hinder the members of the School Board of Glasgow from taking the matter in hand at a very early date. The admirable educational organisation under their care cannot be considered complete without such provision.

The statistics already quoted (excluding the eighteen cases of deaf-mutes) show that one fortieth part of the total number of cases recorded at the Glasgow Ear Institution during eighteen months were practically deaf. All those forty patients were above the age of ten years, and retained the faculty of speech in a more or less perfect degree. Five of the forty were between the ages of ten and fifteen years, and might therefore attend a public school, if oral instruction were given there. Twenty-one were between the ages of fifteen and thirty-five, and the remaining fourteen were between thirty-five and seventy-two. All those thirty-five persons were beyond school age. One young woman among the number had received no systematic instruction whatever, and was unable to read or write. A considerable number of these patients could only write and read with difficulty, and very slowly. The large majority of these forty deaf people were at work, and found themselves at a great disadvantage when deafness overtook them. Some had lost their situations on account of their affliction, and were unable to find employment. For all such persons who lose their hearing after school age, there is no accessible means provided for acquiring lip-reading, of which they stand so much in need. Private tuition only very few can afford. Moreover, such people cannot leave their work or business during the day-time.

All must admit that instruction by the oral system is specially adapted for those who have lost their hearing. Retaining, as they do, their speech, they are already in possession of a large part of the benefit offered by that system of instruction. Only defects in articulation require attention, and in many cases the slight hearing that may remain enables the pupil to impart modulation and tone to the voice. When a person becomes deaf, he instinctively endeavours to compensate for the defect by using his eyes to read the lips of the speaker who addresses him. The art of lip-reading is therefore initiated in this way, and, in order to make its acquisition perfect, systematic instruction is required.

People who lose their hearing are very much disinclined to associate with the finger-speaking deaf and dumb. It is their earnest desire to retain the means of communication with their speaking and hearing neighbours, very few of whom are acquainted with the finger alphabet. The digital signs are much easier learned than oral communication. Deaf children, therefore, resort to signs readily, being ignorant and careless of consequences. Deaf adults are alive to the importance of speaking and lip-reading; so are the parents and guardians of deaf children, and make eager inquiry regarding the oral system in favour of which they always express themselves, and if they do not carry it out, the expense alone prevents them. For that reason they find they must either place their children in asylums or institutions, or neglect their education altogether.

The adult deaf people of Glasgow have formed themselves into an association, and with the assistance of a few friends have provided systematic instruction for themselves in lip-reading. They have already obtained the services of a trained teacher of lip-reading and articulation. The meetings take place in the evenings in the rooms of the Ear Institution, and good progress is being made.

MASSAGE.[1]

By Adolphe Wahltuch, M.D.,

honorary physician to the hulme dispensary, manchester.

Muscular contractions in the human body came, for the first time into play, when the first human being, ever existing, began to breathe, to take nourishment, and to move abont in this world. Regular muscular exercises, or medical gymnastics, are recorded in early literature of the Hindoos and Chinese. The oldest book of the Hindoos —the "Susruta," and of the Chinese the "Cong-fù,"

[1] A paper read before the Clinical Society of Manchester, on February 19th, 1889.

contain illustrated descriptions of medical gymnastics. At all times, and amongst all nations, methods of healing diseases by mechanical means were and are practised. The gymnastics of ancient times, as practised at the Olympic games of the Hellenes, and in the arena of the amphitheatre by the Romans, were healthy exercises, and intended to strengthen the body, but they were one-sided and often injurious. There was wanting the chief element of modern gymnastics—the equal development of all parts of the body. The gymnastics of the ancients were impotent against indolence and corruption of manners, and thus became merely a play-work of a degenerate race. The Teutonic races, living in a primitive state, led a hunter's and a warrior's life in woods and fields, had plenty of outdoor exercise, and thus practised natural gymnastics. Their characteristics, according to Tacitus, the historian, were temperance and purity of manners; but later on they became affected by the corrupt morals of other nations; their powerful constitution was undermined through the concentration in towns and the worrying demands of civilisation, which confined them more to indoor and sedentary occupations. Science came to the rescue and provided new kinds of gymnastics more in accord with the requirements of the age. German athletics, Swedish movement-cure, modern massage, with rational and more natural habits of life, are directed to strengthen the healthy, and to invigorate the weak parts of the body, and to benefit in consequence the over-taxed mind.

Modern massage forms now a special branch of therapeutics, and is gaining daily in popularity and usefulness. Dr. Metzger, in Amsterdam, has done much to demonstrate in practice the advantages of massage as affording relief to numerous sufferers, several reigning sovereigns having derived considerable benefit from his treatment. Massage means the manipulation of the soft parts of the body by stroking, rubbing, tapping, beating, or kneading, with a view to accelerate local circulation of blood, or lymph; to induce absorption of fat or of other unhealthy deposits in the skin, muscles, or joints; to excite muscular contractions; to modify beneficially the nerve-current in various local or general neurotic affections. Massage is effected by the human hand, so well adapted for the purpose. A variety of effects may be produced by using, according to circumstances, the tips of the fingers, the thumb only, the knuckles, the edge of the hand, the fist.

There are four terms expressive of the various manipulations in massage: 1. Effleurage, 2. Pétrissage, 3. Tapotement, 4. Friction.

1. *Effleurage.*—Stroking with the palm of hand, the tips of fingers, the thumb, the knuckles, or the edge of the hand. Effleurage has a soothing effect and relieves pain from tension, neuralgia, etc.

2. *Pétrissage* consists of pinching, pressing, squeezing, rolling and kneading. To be done centripetally, from periphery to trunk, in direction of the current of the lymphatic or veinous vessels. This excites action upon the lymphatics and capillaries, stimulates circulation, promotes absorption, and improves nutrition.

3. *Tapotment.*—Tapping, percussing, tickling, hacking, thrusting, used for deeper muscles of the loins and back.

4. *Friction.*—Rubbing for superficial purposes.

To be more explicit: pressing is done with the thumb; tapping, the tips of the fingers slightly bent (useful in neuralgia of face and cranium); thrusting, using the finger-tips with extended hand; hacking, done with edge of hand, fingers kept apart or together; pinching, keeping thumb on one side and the four fingers on the opposite side, like a pair of pliers; squeezing, same as pinching, but the thumb alone coming into play, the fingers remaining passive; rolling and kneading, using both hands, thumb of both hands on one side, and the four fingers of the two hands on opposite side and manipulating like making dough. In addition to these movements of the limbs, at first passive, then active, are effected, consisting of flexion, extension, pronation, supination, rotation. These movements must be performed at first gently, and by degrees more energetically. The patient at first remains passive, the operator performs the movements for him; in active exercise, the patient performs these movements whilst the operator offers the resistance. The best costume for the patient is a suit of flannel.

Dr. W. S. Playfair says of massage (*Lancet*, January 7th, 1888):—"I would strongly urge everyone contemplating the treatment of a case in this way, either to do it thoroughly and well or not to do it at all." Further, he remarks: "Massage is contradicted in organic disease, but beneficial in functional affections."

Diseases in which massage is of undoubted benefit:

1. *Rheumatism and Neuralgia.*—Massage is useful in muscular rheumatism and in neuralgia, if not due to inflammatory condition. How many are relieved of pain by the use of some ointment, but in such treatment a kind of massage is employed in addition, as the ointment simply applied is not efficient, unless it be well rubbed in. The chief object is the local acceleration of the blood-current, and removal of accumulated morbid waste, or the production of molecular change in muscular or nerve tissue. These effects are easily obtained by massage alone, without the fatty or alcoholic adjuvants in ointment and liniment. Neuralgias may be due to anæmia or hysteria; in such cases massage and passive and active movements will increase the oxidising power of the blood and improve nutrition generally. No doubt the internal administration of tonics, and proper hygienic measures will act as desirable adjuvants. I have used massage in sciatica, in lumbago, and in neuralgias, with marked improvement; in fresh cases one or two applications gave undoubted relief. I applied gentle stroking at first, then pressing, kneading, and finally hacking; time: fifteen to thirty minutes. In sciatica I also used flexion of thighs ten times in a horizontal position, then in a sitting position; I grasped the shoulders, bending the body forward. After a short rest, I recommended a sharp walk out of doors.

2. *Chorea.*—In the Hospital des Enfants Malades in Paris, ninety-five cases, which had resisted all other forms of treatment, were recorded in 1851, as cured by mechano-therapeutics. Dr. Sée places the treatment by massage and movement-cure of choreic children in the front rank of therapeutic measures. As the result of numerous observations, N. Laisné arrived at the conclusion "that none of the means hitherto employed against chorea can show such a uniform success as mechano-therapeutics, and that with the arrest of incoördinate movements, the general health of the child markedly improves, so that not only the chorea but the accompanying anæmia is cured as well." Du Bois Reymond states, "muscular exercise is not exercise of the muscles alone, but exercise of the brain and cord as well." Johannes von Müller, another great physiologist, says, "Perfection in bodily exercise consists often as much in the suppression of useless movements as in the acquirement of those desired." We must admit that in chorea by massage and movement-cure the brain is

directed to recover its equilibrium; the reflex and irregular movements become coördinate to the will and regular.

I have lately used massage in a case of severe chorea, after acute rheumatism, in a girl, æt. ten years, and noticed remarkable and speedy improvement. She suffered from anæmia, and after a month's treatment the pallor disappeared, and the child felt stronger and healthier.

3. *Obesity*.—I have used massage in three cases of adiposity of abdomen, and in each case have observed the gradual diminution of fat.

(1) Miss M——, æt. thirty, general obesity, and especially of abdomen, varicose legs, piles, irregular bowels, capricious appetite, flatulency, shortness of breath. After four months treatment fat considerably reduced, bowels became regular, no flatulency, breathing easy, and appetite good.

(2) Mr. C——, æt. seventy, general obesity, fatty heart, slow digestion, flatulency, faint feeling, shortness of breath. Improved considerably after six months' treatment.

(3) Mrs. E——, æt. thirty-six, habitual costiveness, irregular menses, abdominal walls flabby and fatty. After two months' treatment the bowels began to act regularly, and the catamenial periods formerly every six or seven weeks, returned regularly every four weeks; the abdomen felt firm, and there was a diminution of fat.

I have no doubt now that fatty deposits speedily disappear after prolonged massage, and shall recommend it in all cases that may come under my observation. Dr. Rossbach remarks, "muscular exercise does not increase the elimination of albumen or other nitrogenous compounds; consequently massage does not diminish the real source of maintenance of power."

4. *Arthritic Joint Affections*.—Billroth reports favourable results observed by him during the use of massage at his clinic. Schreiber recommends gentle manipulations, and cautiously executed passive movements. He mentions a case of a lady, aged thirty-five, who had been unable to walk for two years on account of pain in the right knee; she had never borne children, was well nourished, and gave no evidence of hysteria. Continuous treatment lasting four months permanently removed both the pain and the disability to walk. Billroth, speaking of sprains and chronic rheumatic arthritis, says, "I can only agree with the opinions of my colleagues, Von Langenbeck and Esmarch, that for suitable cases massage deserves more recognition than it has received during the past few decades."

5. *Paresis* not due to organic disease; gentle treatment by stroking and pressing produce reflex stimulation of the motor tracts; passive and active exercises. Erl recommends massage as a means of hastening the cure, but always uses electricity in the treatment of milder as well severer forms of paralysis. Dr. Stretch Dowse says, "My growing experience leads me to the conclusion, that massage and electricity should always be employed in association; frequently by the aid of the two success is obtained, whilst each singly produces only a slight effect."

6. *Narcotic Poisoning* by opium, morphia, chloroform, chloral. Beating, pinching, hacking of the muscles over the whole body; stroking, tickling, or whipping with rods the palms and soles. Schreiber considers this treatment far superior to the application of electricity, sinopisms, ammonia. Successful cases are reported by R. Levi, of Venice, in a pamphlet "On the Effects of Flagellation in Narcotic Poisoning." Graves and Barratt report cases of recovery from opium poisoning by applying a few supple willow switches vigorously to the palms and soles. Dr. Bullar, of Southampton, claims to have saved every case in which there was suspension of respiration following chloroform narcosis, by persistent slapping of the patient's body. Dr. Meyer, of Chicago, reports a case of chloral poisoning, in which flagellation was instituted several hours after the drug had been taken, and that consciousness soon returned.

7. *Abdominal and Pelvic Swellings*.—Dr. Semianikoff (*Lancet*, February 9th, 1889) is reported to have obtained in twenty cases of chronic pelvic inflammation and ovaritis high results by abdominal massage. Von Winiwarter regards abdominal massage as indicated in all cases of ovarian cysts, where from any cause operating is impracticable. He recommends it further for any deep lying abdominal tumour, the nature of which is obscure, and remarks, "I am quite ready to shoulder the responsibility for the mildly comical aspect which appears to lie in the proposition of treating abdominal affections by fisticuffs!"

8. *Eye Diseases*.—According to the unanimous opinion of the most eminent oculists, massage is beneficial in the following diseases of the eye: conjunctivitis pustulosa, conjunctivitis marginalis hypertrophica, episelcritis, corneal opacities following pannus and scrofulous and parenchymatous keratitis.

9. *Eczema*.—After an attack of acute eczema I noticed some slight infiltration in my legs. I applied daily after my morning bath centripetal stroking for a few minutes, and in a fortnight these infiltrations entirely disappeared.

A new variation of massage is the treatment of pain by mechanical vibration. In hemicrania R. Vigouroux used, with success, a tuning-fork mounted on a sounding board, and set in vibration with a fiddle bow. The application of the fork to the supra-orbital region transmitted the vibration to the nerve and alleviated the pain.

Some time ago I read a paper on "Electro-therapeutics," and some gentleman present, taking me for an enthusiast, remarked that I was of opinion that electricity would cure everything. I do not admit such an imputation, but am convinced that much suffering can be alleviated and eradicated by the judicial administration of electricity. Massage, coming now into fashion, promises much, yet we must not expect it to replace other treatment. We ought to use it in appropriate cases only, and even in these in combination with other treatment, such as electricity, drugs, etc., at the same time placing the patient under the most advisable hygienic regulations.

SUGGESTIONS FOR THE MORE RATIONAL THERAPEUTICAL TREATMENT OF RESPIRATORY AFFECTIONS.[1]

By C. CLARK BURMAN, L.R.C.P., L.R.C.S. Edin.,
BELFORD, NORTHUMBERLAND.

(*Continued from page* 135.)

I HAVE already said that narcotics encouraged the tendency to dyspnœal attacks, which are of such common occurrence in chronic bronchitis with emphysema or cardiac complication. I explained this by showing that

[1] [To the writings of the late Dr. Milner Fothergill, whose recent decease the profession still mourns, I must express my great indebtedness, not only for suggesting the line of thought I have endeavoured to follow in this paper; but also, as the readers of his works will observe, by the numerous quotations, for the actual words in which to express my meaning. I take the opportunity, therefore, at this stage to fully acknowledge this assistance in a general way, and thus avoid a repetition of references. For further information I would suggest a careful perusal of the following works of Dr. Milner Fothergill: "The Antagonism of Therapeutic Agents," "Chronic Bronchitis," "Handbook of Treatment," "The Physiological Factor in Diagnosis," and "Gout in its Protean Aspects."]

the "sentinels" were drugged, and were not capable of raising an alarm upon the first appearance of danger, but allowed the carbonic acid to increase to a greater amount than usual, before the respiratory centre was sufficiently aroused, thus making the attacks of dyspnœa longer and more painful. The effect of narcotics upon the higher centres is communicated to those at the base of the brain, and prevents the rapid performance of those respiratory actions which purify the blood and allow respiration to become calmer. One or two cases (collected from Dr. Milner Fothergill's works) will show their effects.

1. "A gentleman, who suffered from recent valvular disease, was sent to one of our famous health resorts. He had severe 'heart cough' (from engorgement of the lung with blood), for which his medical attendants there gave him opium. He grew worse, and they pushed the dose. He felt dying, and sent for a medical friend in town to bring him home 'dead or alive.' This gentleman tells me it seemed much more likely to be the former than the latter. The poor fellow was gasping for breath when put into the invalid carriage in the train, yet he slept three hours on the way, and awakened up to drink a glass of milk. Escaping from the influence of the deadly narcotic, the respiratory centre could carry on the respiration without the necessity for voluntary effort. He reached home alive, and what is more, has steadily improved since he got away from the range of the deadly sedative."

2. "This patient suffered from chronic bronchitis with emphysema; had long taken narcotics to induce sleep, under a physician as a private patient. He could not sleep without a narcotic, and then woke up constantly with an attack of dyspnœa during the night. I explained to him that, in my opinion, the attack of dyspnœa was due to the effect of the narcotic, and prescribed for him ammonia, nux vomica, and digitalis. After the first night he had no more dyspnœa, and could lie down and sleep like other people without feeling the need of a narcotic."

3. "A gouty gentleman, with a gouty heart, the hypertrophy of which was failing, with an irregular pulse, complained chiefly of difficulty of breathing, aggravated by flatulence. The breathing was persistently difficult, and in the night he was subject to distressing attacks of dyspnœa (uræmic), which tried him sorely. He also had much itching of the skin. He had acquired, a few years ago, the habit of taking some Battley's sedative for a very painful affection, and continued it, apparently not being able to abandon it without suffering. He always had some at bedtime, as without it he could not sleep. Seeing that it was clearly undesirable to stop the opiate, I put him on strychnia. In a fortnight the attacks of dyspnœa had entirely disappeared; the pulse was improved, and the œdema was reduced."

4. "A gentleman of literary habits, gouty, with corded arteries, irregularly acting hypertrophied heart, chronic bronchitis and emphysema, and great vesical irritability. He habitually took chloral at bedtime, and almost every night had an attack of dyspnœa. His nose, cheeks, and hands were of a blue hue, from the paralysis of his peripheral arterioles by the chloral. I commenced by giving him some ammonia, nux vomica, and digitalis. He improved very considerably, and all but lost his attacks of nocturnal dyspnœa. But the strychnia so excited his irritable bladder centres that it had to be stopped, and belladonna was given in its stead."

5. "A patient was taken into the West London Hospital with emphysema and aortic stenosis. In spite of rest, digitalis and ammonia, he was liable to attacks of dyspnœa, which had come on since his admission into hospital. On searching for an explanation it was found that the house-surgeon had benevolently prescribed chloral for the sleeplessness complained of. This was at once stopped, and the attacks of dyspnœa never returned."

These cases will illustrate the dangers to be avoided better perhaps than any words of mine; but I would particularly direct attention to case 3, where, though the narcotic was continued, its depressant effects were counteracted by the strychnia. That it is occasionally necessary to give one or other form of sedative for the purpose of securing rest, or allaying pain or cough, or both, is admitted; but the drug used must be combined with atropia or strychnia to prevent its depressant effects; either the hypodermic use of the combination already spoken of or in the form of draught, pill, etc. The bromide of ammonium is free from the dangers attached to opium or chloral, and might be tried. But, before prescribing any sedative whatever, I prefer to try the effect of a medicinal dose of alcohol, not taken for its stimulant but its narcotic properties, about two ounces or so, according to the condition of the patient. The greater the respiratory embarrassment the greater the danger from narcotics. In his work on asthma, Dr. Thorowgood, in speaking of complicated asthma, says, "Sedatives at night do not interfere with other remedies during the day; but it is well not to be in too great a hurry to resort to them, for it is not uncommon to find such a medicine as nux vomica overcome spasm, and give the patient a better night's rest than anything else that has ever been tried in the way of an anti-spasmodic or sedative."

In my opinion the bulk of our patients suffering from chronic bronchitis, with emphysema or cardiac complication, who are subject to attacks of dyspnœa coming on when at rest, and especially during sleep, will derive most benefit from the administration, *regularly*, of belladonna or nux vomica, ammonia and digitalis, according to the proportionate amount of influence upon the dyspnœa from pulmonary or cardiac causes. If the cardiac element preponderate, nux vomica and digitalis must be given; if the respiratory embarrassment is due principally to pulmonary conditions, then ammonia or belladonna; but in both forms, nux vomica is highly beneficial. For the purpose of relieving the attack, Hoffmann's anodyne (sp. eth. sulph. co.) in ʒ ss. or ʒ i. doses is very useful; and a large warm poultice over the heart in cardiac cases wonderfully assists the labouring right ventricle. In more severe cases, the hypodermic injection of a combination of morphia and atropia has proved very successful in my hands.[1]

Since failure of the heart is so common a cause of death in chronic affections of the respiratory organs, the use of drugs which shall stimulate the heart, and at the same time

[1] "Treatment of Dyspnœa in the Emphysematous by the Elastic Respirator."—Dr. Bazile Féris (*Bull. Gen. de Thérap.*, August 15th, 1883), considering that dyspnœa in emphysema is produced by loss of elasticity of the alveolar walls, the lungs being hence kept in the position of inspiration, has designed an apparatus to facilitate expiration, and thus restore to the lung its lost elasticity and abolish the dyspnœa. The apparatus designed is extremely simple, and can be easily worn. It resembles exactly a double hernia truss. From a pad situated between the shoulders, the two limbs of the truss pass round under the arm-pits to the terminal pads in front, which are rather larger and thinner than those of a hernia truss. Light straps passing over the shoulders keep the pads in position. The parts at which these pads should be made to exercise pressure are the least resistant parts of the thoracic walls, usually the upper and anterior part of the chest, over the cartilages and the ends of the ribs. The first effect of the pressure

give power to the feeble respiratory act, is highly necessary, and from none other do we meet with better results than from belladonna and nux vomica.

When speaking of the embarrassment of the respiratory function, it may be remembered that I drew attention to the connection existing between it and the action of the skin, as noticed in the profuse sweats of phthisis, and remarked that if the patient did not sleep much he did not sweat. I also showed how this cutaneous secretion seemed to come to the assistance of the lungs, and quoted Carpenter and Hermann in proof of this. At the same time I mentioned the fact that if a phthisical patient got a narcotic to induce sleep, the sweatings were profuse in proportion as the sleep induced was profound or not. If we look upon the perspiration as being vicarious in its nature, at first sight we might suppose it would not be a rational procedure to interfere with it; but I showed that it was a most expensive way of assistance, because the loss of the valuable blood-salts in the excessive secretion from the sudiparous glands enfeebled the already weakened system, and suggested that a more advantageous plan would be to do away with the necessity for this vicarious action of the skin by stimulating the respiratory function. The treatment of sweating by atropine certainly does this, though perhaps its administration is not effected with this object in view. Atropia is known to produce a direct influence upon the sudiparous glands; but when given in phthisis, I imagine its action on the respiratory centre is the chief way in which this particular good effect is produced, by doing away with the necessity for cutaneous action through its stimulation of the respiratory centre, making the act both stronger and deeper.

From a great many clinical observations it seems to have been agreed upon that atropia is decidedly more beneficial than other remedies—such as oxide of zinc, agaricus, picrotoxine, etc.—for the profuse perspiration of phthisis, and probably its superiority over these named drugs is due to the action just mentioned. There are undoubtedly many other questions connected with the treatment of the various complications associated with chronic bronchitis, as well as the functional imperfection of the respiratory act met with in cases of primary cardiac disease, which might with propriety come under discussion here; but many of them, upon reflection, will be found to fall into the category of some of the more prominent symptoms of dyspnœa we have just considered, and their treatment will, as a general rule, be found to come within the compass of the remarks already made. Some, no doubt, must be treated according to the indications presented by individual cases; still, the principles I have endeavoured to lay down will be worth bearing in mind, and will serve as useful points, the relation of which to almost all cases cannot be over-estimated.

I concluded my first part with a few remarks upon whooping-cough; and having then somewhat fully discussed the indications upon which our treatment is based, little is left for me here but to particularise some of these indications. Opinion is still somewhat divided upon the etiology of this affection, but the latest authority upon the subject to which I have had access—viz., a prize essay, to which the Medical Society of London awarded the Fothergillian Gold Medal for 1881, by T. M. Dolan, F.R.C.S. Ed.—is decidedly in favour of the germ theory. The reasons which the author gives for including whooping-cough among diseases having their origin in one of the many forms of germ, are: (1) It is simple; (2) it is in harmony with ascertained facts; (3) it explains many of the phenomena; (4) it has been, and may be, verified. But as I am more interested here in considering the treatment, rather than the pathology or etiology of the disease, I would refer my readers to the essay just mentioned, when each one can judge for himself of the respective value of the statements made by the author.

At present, the evidence for the germ theory is so favourable as to have convinced my mind; and as I stated in my first part, we ought to look for most successful treatment to follow the use of some of the so-called germicides; but I am decidedly of opinion that in this affection—as well as others in which the germ theory is almost unanimously accepted, for instance, in typhoid fever—the alterations in function or structure of certain organs through which the disease manifests itself are to be looked upon as points of interest in the treatment, in addition to the *fons et origo mali*. The old adage, "Remove the cause, and the effect will cease," is scarcely applicable in its integrity to some of the diseases in the class mentioned. In typhoid fever, for instance, the effects of the introduction into the system of the bacillus are so considerable, involving, as they do, not only functional, but structural changes, it would be sheer folly to continue an anti-zymotic treatment alone. We treat the manifestations as well as the cause, and in doing so are rewarded with correspondingly greater success. Giving sulphites, etc., without paying attention to such food as may be assimilated easily, and may produce the least possible disturbance of the ulcers of the ileum, or neglecting the hæmorrhage resulting from these ulcers, would surely be condemned as irrational and unscientific. So, in the treatment of whooping-cough, I hold that the introduction into the body of a *contagium vivum*, whatever it may be, induces a catarrh of the respiratory tract, with hyperæsthesia of the terminal ends of the nerves supplying this tract; so that slight causes induce paroxysms, which paroxysms are the result of the nervous excitability consequent upon the multiplication in the system of the *contagium;* but that these paroxysms, when established, may be kept up by the nerve irritation alone is proved by their recurrence during convalescence, or even after, by exposure to cold, etc.—a mere trick of the nervous mechanism, falling back from custom into its late habit. When once established, they may be retained, or recur from other causes than those upon which they were dependent for their origin. If, then, we find a catarrhal condition of the respiratory tract associated with intense excitability of the nerves supplying it, rendering nervous explosions liable to occur from slight causes, a treatment which combines a sedative of this nervous irritability with that of a germ-destroying agent might be looked upon as one most likely to produce the best effects. This theory is, I think, supported by experience.

But theorising abstractly is very easy, compared with the best treatment to be adopted in an epidemic of whooping-cough where our theories are ruthlessly discarded. We seldom find any disease, or class of diseases, run a course such as is so precisely laid down in our text-books. We

is to drive the air out from the chest, thus aiding expiration. Inspiration follows naturally, the inspiratory muscles being increased in volume. Tracings show increased movement of the chest, when the apparatus is worn. The cases in which M. Féris has tried his respirators have been relieved of their dyspnœa in a remarkable manner. The benefits conferred can be confirmed by experiments with the spirometer, the volume of air respired being found to be nearly double that breathed without the apparatus (*London Medical Record Report*, 1862, January 15th, 1884).

must be prepared for modifications, for complications, and other occurrences, which will upset the theories foremost in our thoughts when we first began the treatment of an epidemic; and it is these modifications and complications that we have most frequently to treat medicinally. I dare-say one-half or two-thirds of all children suffering from whooping-cough pass through it with nothing more than domestic treatment, which frequently can hardly be dignified by the name medicinal; so that we may assume the tendency is to spontaneous recovery, provided due care be taken to prevent the catarrhal condition of the respiratory tract passing on to something more serious. That there is no such thing as a specific for whooping-cough can be easily proved by the numerous remedies which have been tried with but a varying amount of success. I think our proper consideration of the influence of the effects of constitutional diatheses, hygienic surroundings, carefully selected food, and times for feeding (the latter being most important), and the presence or absence of complications, will be our safest guides to therapeutic measures. Some require little or no treatment, others tax all our skill to preserve life when a complication such as capillary bronchitis is found co-existing; and not unfrequently the most persevering therapeutic treatment, combined with the greatest ability in wielding our weapons of defence, is alike useless, and our patient sinks. According to the reports of the Registrar General, 109,454 deaths were registered from whooping-cough in England and Wales from the year 1860 to 1869. I am far from laying the blame of such a high death-rate to the charge of the profession. I am quite aware that a great many of the deaths are due to the ignorance and thoughtlessness of the friends; but I do think that some definite plan of treatment, based on broad lines, so as to include the chief complications, might be laid down, instead of the indiscriminate methods of treatment now in vogue. My readers will pardon me if I attempt to lay down such a line, founded on the indications (mentioned above) of diathesis, hygiene (including food), and complications.

1. *Diathesis.*—We are all thoroughly conversant with the immense influence exerted by diathesis upon acute diseases in particular. Perhaps this influence is most marked in those affections involving the respiratory organs. It not unfrequently decides whether a simple catarrh shall pass off entirely in a few days, or be the starting-point of that scourge of our land—phthisis. In whooping-cough we meet with the constitutional *versus* the local condition. An attack in a strong healthy child, free from all taint of diathetic disorder, passes off with no residuum. The catarrh remains, as such, until recovered from; but in the case of a well-marked strumous child we find an entirely opposite condition of affairs. He not only suffers more from length of actual attack, but the catarrh is more persistent—tends to degenerate or extend. This is owing, no doubt, to the feeble vital processes in which, from the growth and development going on, no surplus energy is available; and the newly-formed products are either of a low degree of vitality, or the absorptive powers are unable to remove effectually the products resulting from the sub-acute inflammatory condition. They remain and degenerate, or are re-absorbed and deposited in other parts, forming the nucleus of a destructive process.

In an attack of whooping-cough occurring in a child, the subject of some diathetic temperament, we should look not so much to the disease as to the individual, and use every means in our power to enable the disease to pass over without leaving permanent traces. In other words, we think not so much of the storm, but how best to enable the frail vessel to outride it, and to continue the voyage of life safely with no other injury than time with proper care will remove.

The medicinal treatment of such cases is greatly assisted by the exhibition of good food with satisfactory hygienic surroundings. It is during convalescence we look to the administration of those remedies known to influence the absorbents, which improve the condition of the blood, which provide the elements for healthy growth, and encourage the natural tendency for the return of those conditions existing previous to the attack, or possibly to improve upon them. Here we find the benefit of the syrup of iodide of iron combined with Parrish's syrup, cod-liver oil, the various preparations of malt, etc.

The due consideration of the diathetic tendencies of our patient during any acute disease, and more especially diseases affecting the respiratory organs, is apt to be underestimated. Sir James Paget, in a clinical lecture, delivered after his recovery from *post-mortem* poisoning, calls attention to this important factor both in diagnosis and treatment. He suffered from two distinct attacks of pneumonia during his illness, which he attributed to his diathetic tendency, and not to any septicæmic influence. He says, "Keep such facts as this in mind. They show that there is no disease so specific but that its signs may be confused or complicated with the things that are peculiar to the patient. . . . . This is not a mere question of doctrinal pathology. It is among the first necessities for success in practice that, in the several phenomena of a disease observed in any patient, you should be able to estimate what belongs to the disease, and what to the man. A farmer may as well expect success if he sows his fields without regard to their soils, or to the weeds that may 'of themselves' come up in them, as one of us may expect it if we treat diseases without exactly studying the constitutions of those in whom they occur" ("Clinical Lectures and Essays," 2nd edition, pp. 336-7). In the same work, at p. 401, the essay on the study of constitutional diseases carries the argument still further, and will amply repay careful perusal. In a recently published work entitled "The Pedigree of Disease," at pp. 21 and 22, we find similar observations from another of our great leaders: "There can be no question whatever as to the reality of the difference between individuals, nor any doubt as to the importance of the recognition of those differences by the medical practitioner. By far the commonest error of the prescriber, and one which most interferes with his success, is the easy-going habit of regarding all persons as alike, recognising differences only in their diseases; or, to put it in other language, of ignoring the predisposing causes and taking account only of immediate ones. The farmer who would succeed in his pursuits must not content himself with making sure that he has sown good seed, and according to the most approved methods; he must go further back to take knowledge of the nature of the soil with which he has to deal, of the crops which it has previously borne, and of the manures which have been used. It is much the same with us in the diagnosis and treatment of disease. In addition to the primary or exciting cause, which is of paramount importance, we have various other causes, which may perhaps be conveniently classed together under the term 'contributory,' since they contribute to control and modify final results. Amongst these, temperament—the original vital endowment of the

individual—is unquestionably a real force, and one which we would most gladly recognise and estimate if we could."

2. *Hygiène.*—The infectious and contagious nature of whooping-cough is a good reason for proper precautions concerning unsanitary surroundings; but I am dealing rather with the individual, and wish to point out the direct benefits the patient receives from a thorough compliance with the laws of hygiene regarding ventilation, warmth, etc. An impure atmosphere, either from within or without, must be avoided. Hence the advantage of a good lofty room in an upper part of the house, free from the encumbrance of carpets, bedhangings, and superfluous articles of furniture. The temperature should be kept constant at or about 60°, while its atmosphere may be impregnated by some preparation with anti-zymotic properties—carbolic acid, terebene, thymol, eucalyptol, etc.—either by means of a steam or air atomizer, or by direct heat over a gas jet or spirit lamp. By so doing we prevent those constant changes of temperature which are so provocative of paroxysms, and we reduce their frequency and give the mucous membrance the best chance to recover itself.

I look upon the dietetic treatment of whooping-cough as one of the most important matters. To the strong, and still more to the weak, the administration of easily-assimilated and nourishing diet is of paramount necessity; and when vomiting is a marked feature the greatest management is sometimes required to secure the retention of a sufficient quantity. If a paroxysm comes on shortly after food has been taken, the food is almost invariably rejected. This is most likely to occur if the stomach contains any quantity. The best plan is to give little and often, and never to forget that *shortly after* a paroxysm is the best opportunity, for it has a chance of being absorbed before another occurs. The food must be such that the shortest time is required for absorption; milk with soda water, peptonised milk, beef tea, chicken soup, etc., are the chief articles which may be given. As a rule children take milk with soda or seltzer water readily, and when the other preparations are not at hand we can readily rely upon this.

3. *Complications.*—Upon the presence or absence of complications rests the significance of an attack of whooping-cough. In many cases due attention to the plan already laid down may prevent their appearance, or modify them to a large extent; but, unfortunately, either from ignorance or inability to carry out this plan, we find, only too frequently, complications appear, and to them, rather than to the disease itself, is the high death-rate attributable. Here, and I might almost say here alone, does our knowledge, and a proper use of our knowledge of therapeutics stand us in good stead. However unable we may be to combat and cut short the original malady, we certainly possess a marked power over the complications; and since to them we attribute the high mortality, to them we must turn our attention if we seek its reduction.

I have already gone over in detail the two most formidable complications, in the shape of capillary bronchitis and catarrhal pneumonia; others perhaps of greater frequency, but not so dangerous, remain to be considered.

The gastro-intestinal tract often becomes the seat of irritation, commencing with the gastric disturbance which accompanies almost every case; but the plan of giving milk with an alkali—such as soda, potash, or seltzer water—or with lime water, will frequently prevent this. If diarrhœa becomes serious, then small doses of hyd. c. creta, followed up with chalk mixture and catechu or logwood, is indicated.

Hæmorrhages are frequent, but seldom severe, unless the ulcer of the frænum linguæ be torn. They require, as a rule, but ordinary treatment. They depend upon the severity of the paroxysms, of which I shall speak shortly. Other means, besides medicinal, are to be found, which reduce the paroxysmal attacks, and none are more effectual than an agreeable temperature.

I wish now to say a few words upon the general treatment of whooping-cough. In many cases medicinal treatment is uncalled for, unless the paroxysms are excessively frequent, leading to loss of sleep, interference with nutrition, etc. I have already said of specifics we have none; but among the remedies used for alleviating the disease, we certainly possess some of great value. Here, again, a drug which I have so often brought under notice stands highest in estimation—viz., belladonna, or its alkaloid atropia, either alone, or in combination with oxide of zinc, as recommended by Dr. Steiner, of Prague. It may be given during the spasmodic stage, and pushed until the paroxysms are reduced in frequency. Drs. Meigs and Pepper, of Philadelphia, advocate its combination with alum, and Dr. Golding Bird speaks highly in favour of alum with conium. Niemeyer does not believe in belladonna, but in the method of sweating at the commencement of the disease. He gives potassæ carbonatis, and free administration of good diet. Amyl nitrite has been used, mixed with chloroform, as an inhalation, and $\frac{1}{12}$ gr. of cyanide of silver every two hours for three days. Dr. West advocates hydrocyanic acid. Chloral hydrate and croton chloral have been extensively used; but I would beg to call to mind the depressant properties of chloral, and recommend its use, only when the symptoms are free from much permanent respiratory embarrassment.

Bromide of ammonium is perhaps, on the whole, the safest sedative to employ, since its composition prevents it having too great a depressant action. When combined with atropia it is, in my opinion, the best treatment for ordinary cases. Quinine, or tinct. cinchon. co., is very useful; its tonic and anti-zymotic properties are alike good. Gelseminum sempervirens has many advocates. But with all the remedies mentioned, the chief difficulty is to know when they are most valuable. We may, to a certain extent, be guided as to the value of depressant or stimulant drugs according to the state of the breathing during the interval. This I have already mentioned in my first part, as follows:—"There seems every reason to believe that by a careful attention to the rapidity of the respiration, its depth, its character, whether actively spasmodic or gasping and laboured, the agent may be selected which will, with fair certainty, relieve the case in point. When there is excitement both of the respiration and the circulation—for they are so closely linked together, that any marked condition of the one materially influences the other—then there are good grounds for giving bromide of potassium, chloral, or morphia, together with those antispasmodics, musk, camphor, etc., of which we have as yet no certain knowledge from experiment, but simply the legendary lore of a far-reaching empiricism. Where there is evident excitement in the respiratory centre, these depressants may be chosen with much probability of success. On the other hand, when there are evidences of more or less enfeeblement of the centres, and the respiration is laboured and slow, or shallow and rapid, and still more if both shallow and slow, then the opposite class of

agents must be preferred" ("Antagonism of Therapeutic Agents," p. 105).

This brings me to the conclusion of a subject which it was my intention to complete in a single paper, but the personal profit and pleasure arising from the detailed study of it must be my apology for its extension. I can only hope that the theories which have been enunciated, and the opinions which have been expressed, may be criticised in as fair a spirit as that in which they have been laid down. It has been my motive to summarise the elements of our present knowledge on the subject, in order that the practical application of the same may result in an improvement in our methods of treatment of respiratory affections, and other disorders attended with embarrassment of the respiratory act, and bring about a wholesome change in the prescription for them of narcotics (without the fullest consideration)—a practice fraught with the greatest danger, and having attached to it the gravest responsibilities, both moral and professional.

THE OPERATION OF EXCISION OF THE KNEE-JOINT.

By William Thomson, M.A., F.R.C.S.,

Surgeon to the Richmond Hospital, Dublin; General Secretary Royal Academy of Medicine in Ireland, etc.

Observations which have recently been published indicate a very strong desire to avoid the operation of excision of the knee-joint in cases of tuberculous synovitis. Until a few years ago the results in England and Germany were certainly not encouraging. In Germany, of 104 cases, collected by Knoll, and published by Volkmann in 1876 (Sydenham Society), fifty-two died; exactly fifty per cent. England could only show recoveries to about seventy per cent.; and the impression made by these bad results still no doubt exercises an effect opposed to the operation. The results of to-day are, however, an immense improvement on those just quoted. In 1869, Swain's figures showed 472 operations with 116 deaths; but in 1880, Holmes published a list of 245 collected cases with twenty-one deaths directly from the operation, four after amputation; while forty-seven were set down as having failed and were, most of them, subjected to removal of the limb. In Dublin, however, excision has been a much more successful operation than it appears to have been elsewhere. In my own hospital I have only known one death to occur from the operation during the fifteen years for which I have been surgeon, and we have had over forty cases. Many of these were done without the accurate care of modern antiseptic surgery: so that we can hardly realise what are the causes which elsewhere appear to have produced such fatal results.

In this paper I propose simply to state in detail the manner in which we deal with cases requiring excision, because our recoveries for the past few years have been extremely rapid, and so far as preservation of a useful limb goes, uniformly successful. The parts are carefully shaved the day before, and well washed with soap and a brush. For two hours before operation a swathe of lint, wet with weak carbolic acid lotion, is applied to the knee, and for some distance above and below. On the table there is another ablution which ends with a free application of ether.

Incision.—The limb is then Esmarched or not, according to the views of the operator, and an ordinary horse-shoe incision made, beginning and ending as far back as possible over the condyles, and dividing at the first sweep the ligament of the patella, and all other soft tissues. The patella is next removed, and the joint is freely opened by division of the crucial ligaments. The most difficult part of the operation now begins, and that is, thorough removal of all the pulpy tissues. These are freely dissected out with scissors or knife, and the pouch which extends up under the quadriceps tendon is followed. If necessary, the flap is divided by a longitudinal incision so as to make all plain. This does not in the least add to the risk of the operation, and it enables us to make a thorough search into every crevice.

Section of the Bones.—When all the diseased soft tissues have been removed, the section of the femur is made, and then of the tibia. The portions removed depend upon the extent of osseous disease, but if it is possible the epiphysary lines are not encroached upon in young subjects. If there are any soft spots, these are gouged until firm bone is reached. In a case which was recently operated upon by my colleague, Mr. Thornley Stoker, the softening passed so far down into the head of the tibia that it was resolved to make a counter-opening in that bone two inches below the section. The hole was thoroughly scraped out, a drainage-tube was introduced, and the case did well. The saw used is a broad bladed one, with movable back, and it is used from before, backwards, towards the popliteal space, the vessels being protected by a flat retractor. In my early excisions I used Butcher's saw, but I have long since ceased to employ it because of the narrowness of the blade. It is not always easy even with the saw now used to make sections which will allow the bones to fit well when brought together, but with Butcher's saw it was almost impossible to get a level surface, and frequently it was found necessary by further "dressing" to remove the undulations left by the blade upon the divided bone. At this stage there must be a renewed search for diseased parts in the soft structures. When the thigh is brought into the upright position, the leg hangs from it with the sole of the foot on the table. An assistant puts his closed fist into the popliteal fold, and in this way makes tense the tissues which are lying exposed to the operator. Then any pulpy material is clipped away, care, of course, being taken not to expose or wound important structures.

Bleeding.—Every bleeding point must be carefully secured, and the wound made as dry as possible, especially if the limb has been "Esmarched." In the latter case the reactionary hæmorrhage is often sharp, and the surgeon who wants to avoid opening up the wound in a few hours will not grudge the tediousness of this stage. Some of the most troublesome vessels are those in and about the margins of the periosteum; and it will be found that these are most rapidly secured by passing a gut suture under them with a needle, and so tying them. Next there is a thorough irrigation with an antiseptic solution, and all visible tags and débris are removed.

Drainage.—When the divided bones have been found to fit properly, the next step is to provide for drainage. The carrying of the first incision as far back as possible is not quite enough. When the bones have been laid in position there remains a pocket formed by the tissues of the popliteal space, lying on a lower level than the wound-opening at the sides, and into this more or less blood and serum must filter. In my earlier cases I was satisfied with simply leaving the extremities of the skin-wound open;

later on I passed a drainage-tube across the popliteal space immediately behind the bones, withdrawing it on the third day. Afterwards I tried the method of cutting a narrow triangular slip from the margin of the skin-flap, of equal length on either side, leaving the bases however attached. These were tucked in behind the bones, and their extremities were stitched together with catgut, thus helping to keep open a channel from side to side. The result was not as satisfactory as I was led to expect, and I then adopted the practice of draining directly backwards through the popliteal space itself. This method was recommended by Mr. Jonathan Hutchinson, so far back as 1856 (*Medical Times and Gazette*, March 15th), but it has not been generally adopted. A paper, by M. Lucas Championnière, in the *Revue de Chirurgie*, reporting eleven cases of excision in which he employed this method, induced me to try it. There can be no doubt that it is the most rational plan for thorough drainage, and it is the best. The danger of wounding important vessels or nerves is not great if ordinary care be taken. A transverse section of the femur through the condyles shows that the popliteal artery and its accompanying nerve and vein lie in a position practically corresponding to the inter-condyloid notch, and that there is, therefore, ample room on either side of them to make a drainage opening backwards.

For the accompanying outline I am indebted to Professor Cunningham, of Trinity College, Dublin. It is taken from one of his frozen sections, and shows accurately the position of the vessel in relation to the portion of the femur which is actually divided. I have found that the finger tip makes an excellent guide, along which an ordinary scalpel may be slowly passed backwards at one side or other of the artery. Through this opening a drainage-tube is passed, and is retained for a couple of days. After that it may safely be removed.

If it has not been found necessary to divide the flap in pursuit of diseased membrane, it is always well to make an incision through it, corresponding to the space left by the removal of the patella. In practice I have found that the sides of the flap adhere, thus allowing a quantity of serum to collect in the space just mentioned. If an opening be made, and a drainage-tube inserted, it will prevent this accumulation, and will aid in the rapid adhesion of the anterior flap to the surface beneath it.

The tubes having been inserted, the bones are placed in position, and the skin wound is secured. This will be best done by short lengths of continuous suture, say an inch and a half. The material to be used should be preferably fine silk. It is less irritating than catgut, which is so apt to cause small ulcerations at the openings into the skin; it holds for a practically unlimited time, and there is no danger of ripping open the wound by absorption of the stitches as there is when gut is used. When the superficial parts are firmly united, the stitches can be easily withdrawn.

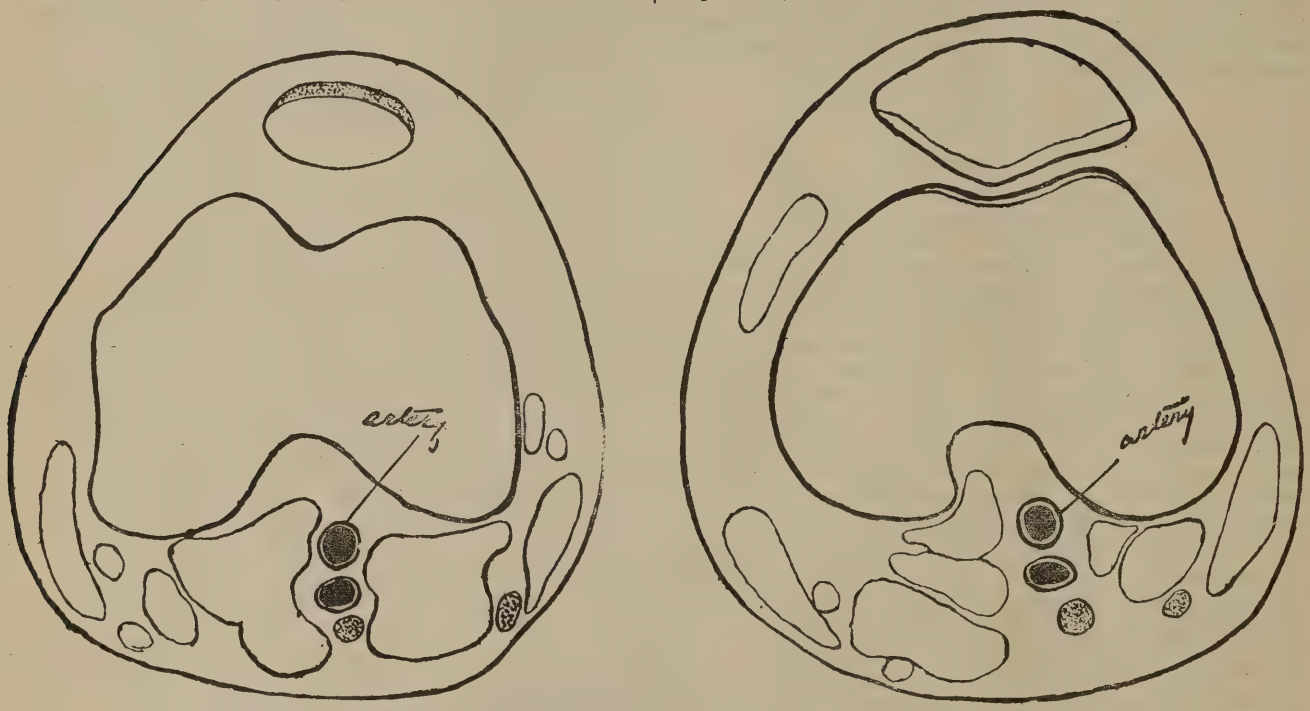

Fig. 1.—Transverse sections through the femur (left limb, upper surface of cut toward the observer).
1. Immediately above the joint.
2. Somewhat higher—
Artery nearest to the bone;
Vein intermediate between artery and
Nerve, which is superficial.

Fixing the Bones.—The great difficulty met with in the after treatment of cases of knee excision, is the keeping of the ends of the bones in just relation to each other. The tendency of the femur to tilt forward so as to lie at a higher level than, or somewhat anterior to, the divided surface of tibia, is often hard to overcome. Moreover, there is always much pain caused by every movement of the divided

surfaces one against the other; healing is delayed by the want of rest, and the liability to suppuration and its consequent risk is greatly increased. Mr. Hayes, of Dublin, has devised a splint in which the portion which supports the leg is thrown forward about an inch by a step, so that the lower part of the limb may be raised somewhat to meet the natural tilting of the femur. Others have suggested suturing with silver wire, silk or catgut. My experience of these last, however, is that they do not afford the quiet solidity and firmness which are essential, and I have therefore adopted the plan of Mr. Thornley Stoker, my colleague, who applies to it the term "dowelling." At the meeting of the Royal Academy of Medicine in Ireland, March 18th, 1887, Mr. Stoker read a paper describing three cases in which he had himself used this method. Curiously enough, a paper by Mr. Morrant Baker was published in the *British Medical Journal*, of February 12th, on the subject, and Mr. Baker has used pegging since 1872. Mr. Stoker was not, however, aware of the practice, and as his proceeding ought to be fully known, I will give his own description of it.

Fig. 2.

Thornley Stoker's "Dowel," about half size.

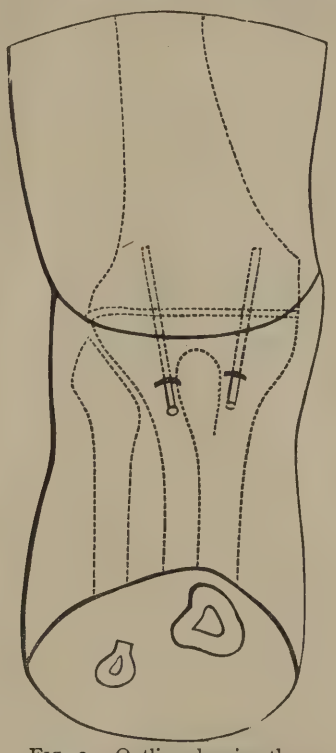

Fig. 3.—Outline showing the "dowels" pinning the bones together

"When the wound is ready to be closed, having punctured the skin on each side of the tubercle of the tibia with a tenotome, I insert a steel awl into the bone at each of these points. The instrument is made to enter the tibia in a direction upwards, backwards, and outwards from the middle line of the limb. It is only pushed into the bone for about three-quarters of an inch, so as to penetrate its compact covering and give the proper direction to the silver dowels afterwards used. A silver wire a shade larger in diameter than the awl, having its end filed to a chisel-shaped edge, is then pushed into each perforation, and the femur, being held in forced relation with the tibia, is made to penetrate the upper bone as far backwards as the compact covering of its popliteal surface. The dowels may be either made to diverge or approximate as they pass upwards. The former direction is best, as they will, when so introduced, give greater fixity and freedom from rotatory motion than when crossed, as directed by Mr. Morrant Baker. They should not be parallel, as they then offer little resistance to vertical displacement. In the cases of very young children, one dowel, introduced in the middle line below the tubercle, and directed upwards and backwards, will be found sufficient. It is important that the dowels should be a little larger than the awl, so as to fit tightly. The size most suitable is No. 14 Birmingham wire gauze—that is, about the calibre of a French No. 7 bougie. The soft edge of the silver passes readily through the cancellous tissue, but with difficulty through the compact layer which covers it; and therefore, with a view to avoid entering the popliteal space, silver should be preferred to the steel recommended by Mr. Morrant Baker. It seems to me to be also preferable to the bone pins recommended by Mr. Howard Marsh, more easily introduced, with less injury of the cancellous tissue, and less liable to give way under any sudden strain. The dowels are then cut half an inch from the skin, and their ends included in the dressings."

The pins are allowed to remain in for about three weeks, and are then removed. I do not cut off the ends. The slightest traction withdraws the dowels, and they can be used over and over again. The surface of the silver remains perfectly smooth, and no irritation whatever has been caused in the cases in which I have used them.

The great advantage of this plan of fixation can hardly be realised until it is put into practice, especially by those who have experience of knee excision under the older methods. The patients are free from the painful startings which follow every jar of the divided ends of the bones together, they sleep tranquilly, and I have seen them sitting up in bed on the third day after operation without being in the least disturbed by that position. A German surgeon (E. Hahn) uses steel nails, which are driven into the bones with a hammer, and are removed some weeks later.

The Splint.—In my earlier cases I employed Dr. Heron Watson's method; and in the *British Medical Journal*, of January 28th, 1882, I gave the reasons which induced me to adopt a simple modification of his splint. I found that a slip of strong hoop iron in front, with a loop over the wound, and a similar slip behind, allowed the plaster bandage to fit closely to the limb, and prevented painful movement of the bones. It was my habit to fix the splint with ordinary bandages for the first twenty-four hours, so as to permit the opening up of the wound in case of hæmorrhage, and then at the first dressing to apply the plaster-of-Paris. A little experience showed me that the limb rested easily, and was firmly held by the ordinary bandage which, including the hoop iron splint, could be closely applied to the limb. I then determined to try a case without any plaster whatever, and for some years I have not used plaster-of-Paris at all. My colleagues observe the same practice, and it has been uniformly satisfactory.

The splint I now use is made of strong hoop iron about 1½ inches wide. It is easily bent into any shape, and it is usually prepared by my resident pupil. The posterior splint is plain, and extends from the gluteal fold to the foot. At the tendo-Achillis it must be bent downwards, so as to avoid pressure, and the continuation is brought up along the sole of the foot. It gives greater support, and

enables us to bandage and fit the foot to it. The anterior splint extends from the groin, over the thigh, is then shaped into a roomy loop so as to give space for dressing, and is continued downwards towards the foot, being finally shaped to lie easily upon the instep. These splints are carefully padded beforehand, and the wadding is fixed in position by a spiral bandage. The dressing should be applied in front, and then be carried down on either side as far as necessary. The splints are then applied, and are fixed with which I am acquainted, and it has the merits of cheapness, simplicity, and thorough efficiency." I observe that Mr. Macnamara, in his last edition of "Diseases of Bones and Joints," 1887, quotes from Sir W. Stokes' paper a description of the manner in which the splint is made and applied, but as he was unaware of my communication already referred to, I may take this opportunity of making it quite clear that whatever merit there is in the method is mine.

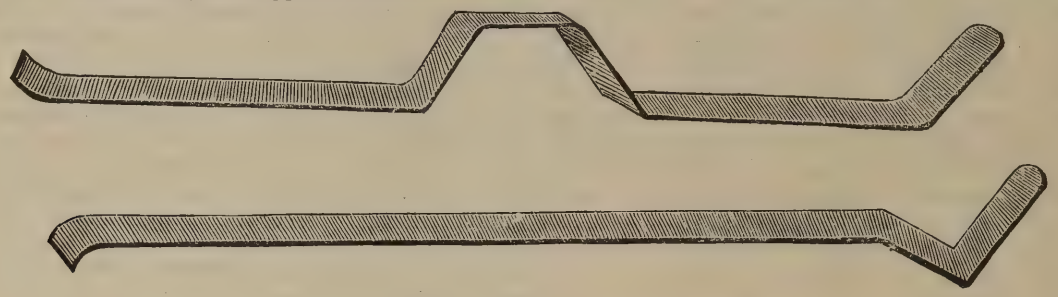

Fig. 4.—Mr. Thomson's Splint for Excision of the Knee.

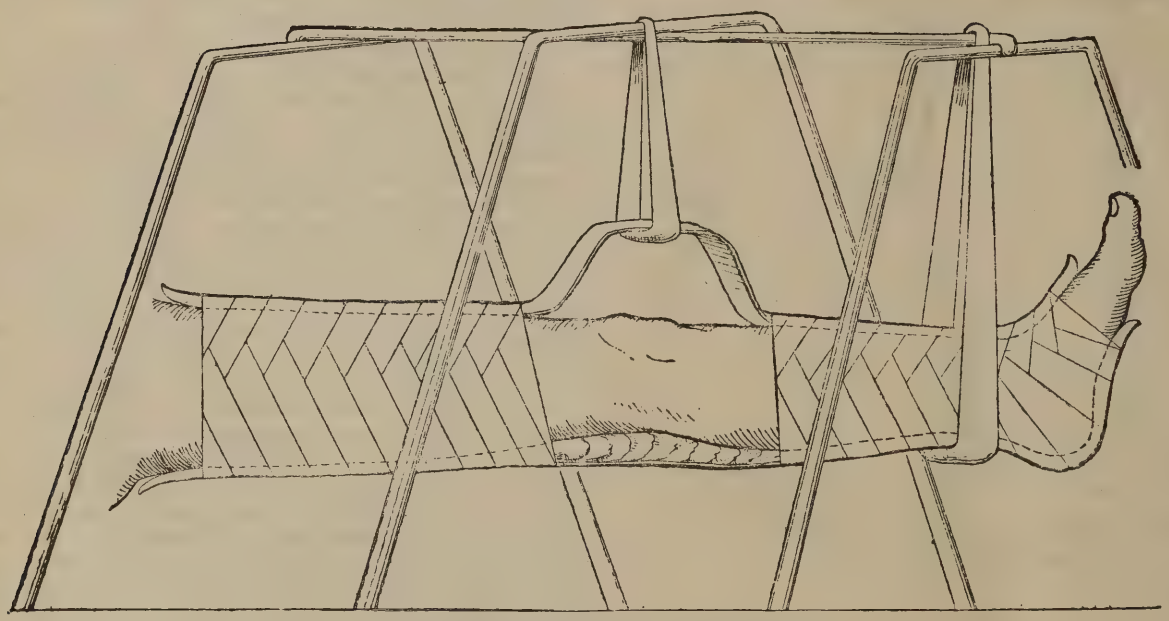

Fig. 5.—Limb with Mr. Thomson's Splint applied.

by an ordinary bandage, and if this is properly employed it will not be necessary to readjust it for some weeks. The last thing done is to pack the popliteal space on either side with iodoform wool, taking care, of course, that the drainage tube delivers all fluids into antiseptic dressing. When the patient has been removed to bed, the leg is swung from a strong cradle. Two turns of an ordinary bandage are passed through the loop, and fixed to a bar of the cradle above, and another bandage is passed under the splint just under the ankle, and also fixed to a bar in the cradle. This permits the patient to make some movement if necessary, and, as I have already said, he is usually able to sit up in bed on the third or fourth day with a bed-rest, suffering no discomfort.

At the Brighton Meeting of the British Medical Association in 1881, Sir W. Stokes said of this plan, "I consider this method of fixing the limb far superior to any others

If the surgeon using this splint should desire to prevent any shifting of it in a restless patient, a very simple and effective arrangement will be found in the following: A piece of thick felt is procured, such as is used in poroplastic jackets, but without any stiffening material. For the leg it should measure about six inches by ten. The posterior splint is laid on the central line of this, the greater diameter being transverse. A few holes are bored through the felt with a bradawl along either margin of the hoop iron. Then a piece of copper wire is passed from behind through one hole, across the iron, and back through the corresponding hole. The two ends are then twisted together. The other holes are treated in the same way, and the piece of felt is firmly secured to the iron. Another piece of felt is arranged in the same way high up on the thigh. It will be found that these soft felt straps adapt themselves closely to the limb, and they can be fastened in front by a lace passed

round a few "eyelet" hooks. The bandage is then applied over all, but the felt pieces will give increased fixity and prevent any movement of the under splint. Moreover, when the patient leaves bed it will be found to give ample strength and support to the limb; but at that period, of course, the foot-piece is dispensed with.

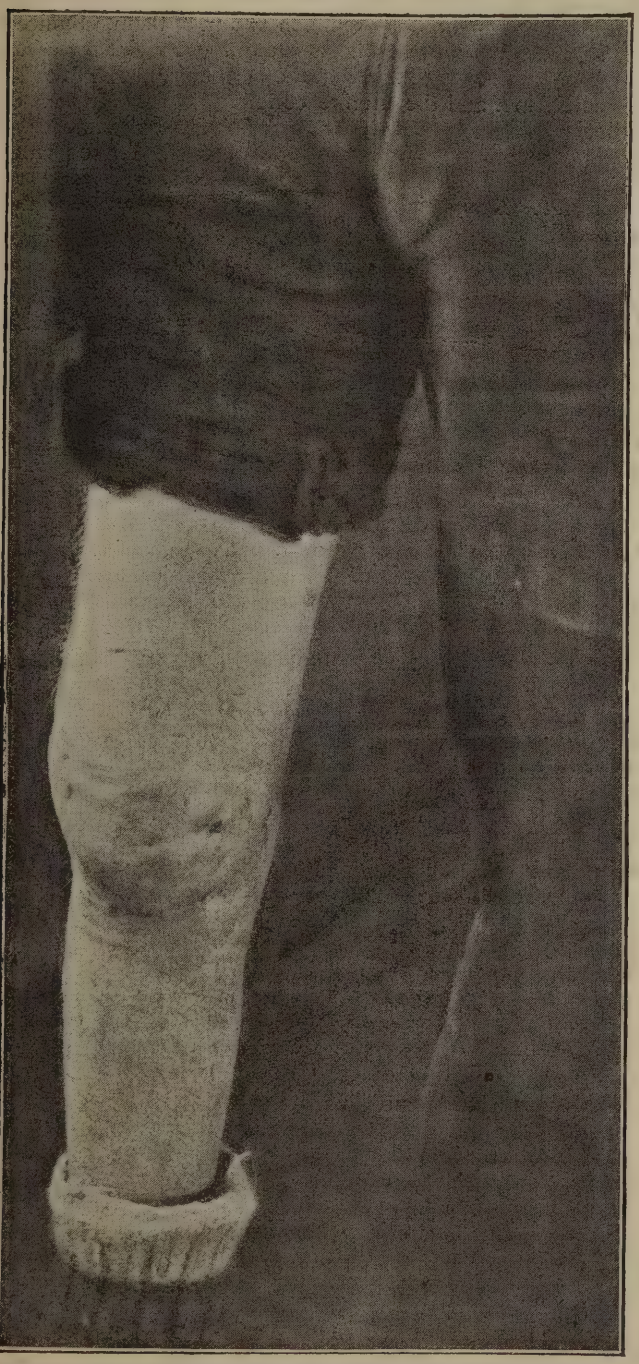

Fig. 6.—Seven Weeks after Excision of Knee Joint (Photograph).

The Dressings.—The first dressing is changed in twenty hours. The drainage-tubes are then removed, and subsequent interference is regulated altogether by the indication given by the temperature chart, or the escape of fluid. The dressing usually employed is, first a couple of folds of alembroth gauze, and over this a thick pad of Hartmann's wood wool. The stitches may be removed in a week or two according to circumstances, and the skin-wound is usually then found healed, except at one or two points. The dowels are taken out at the end of the third week, and the patient may leave bed in about six weeks, with a light splint to give security. Of course, there are cases in which the course is not so rapid as this, but I speak of what are our expectations, based on our more recent experiences. I have, at present, a patient who began to walk in the seventh week.

As to the general results of excision in the Richmond Surgical Hospital, they have been most satisfactory. We have had our troubles in the days before antiseptic surgery was as fully developed as it is now, but we have to deplore the loss of only one life. I have now done fifteen excisions of the knee. In one case the patient was a young lady, living 126 miles away, who was terribly prostrated by hectic, and in whose case amputation would not be permitted. Six weeks later it became necessary to remove the limb in order to save her life, and she recovered. In another case I amputated because the patient developed symptoms of tuberculosis in the right lung, and she also recovered. Compared with the reports of cases twenty-five years ago, there are few operations which have made more way in the direction of safety and utility than this; and in the cases in which the joint is irretrievably diseased, I believe it will give results better than any other. It is, however, important to operate sufficiently early, and not to wait in the hope of cure until the soft tissues are riddled with sinuses, and the bones have been extensively diseased.

THE USE AND ABUSE OF MASSAGE IN GYNÆCOLOGICAL PRACTICE.[1]

By Dr. H. Macnaughton Jones.

It is widely known that the therapeutic agent massage is largely employed at present in a variety of affections to which women are more especially liable; and, not only is this the case in regard to those affections arising from morbid conditions of the pelvic viscera, but the same may be said of a number of unhealthful states, due either directly to these pelvic derangements, or indirectly following as a consequence of them. From sources inside the profession of medicine, and from others outside its pale, the public, which in matters of medical fashion often leads the profession, has learned to believe in massage as a marvellous remedial measure, and as in the past, in other matters, so now in this, the patient and her friends suggest to the medical man the course of treatment he should adopt; or they often go further, and ignoring medical countenance and advice, prescribe this or that plan on their own responsibility. Truly, Mr. Public, once he is gratuitously mis-educated, becomes a veritable tyrant to that profession to which he pretends submission. Nor can we wonder at this vulgar assumption of little knowledge on the part of lay outsiders when we find such catering for the curious in matters medical as the periodical literature of the day supplies. We need express no astonishment if some contemporary periodical is,

[1] A paper read at a meeting of the Gynæcological Society on March 13th, 1889.

in the near future, laid under tribute for an article on "Electrolysis *versus* Mutilation," or "Keithism *versus* Tatism." One of the tests of medical eminence, and stepping-stones to popularity, is an article on some such quasi-popular subjects as "Massage in Neurasthenia," "Alcoholism and Insanity," "Worry and Gout." Then comes for patient a fashionable favourite, or distinguished politician, and then—well, anything.

Now it at times happens that a system or plan of treatment, in itself intrinsically valuable, and capable of most useful application, suffers materially from such vulgar handling. The unavoidable contamination with Charlatanism, educated and uneducated alike, so soils its utility that many refuse to believe that any good can come out of it. They dislike it, and cannot tell why. They do not allow themselves to inquire into its merits, or, rejecting the good and evil elements alike, lose the advantage which such an analysis would have afforded. So it has been with massage. The system has suffered from contamination. The art of the *masseur* has been interpolated with the avocation of the hotel manager, and a resultant of the two occupations is found in the divided spoils of both. Hence *masseurs* and *masseuses* have flooded the medical market, and so-called "homes" for massage are almost as plentiful in certain localities as pawn offices; and if we are to judge by the theory of "demand and supply" they should be nearly as remunerative. It is a fact not to be disputed at the present moment that in London a large number of women, after acquiring a superficial smattering of the most elementary medical knowledge, go about as electricians and *masseuses*, earning, after an investment of £5 in a course of lectures, or for other as-easily-obtained badge of knowledge, or even without this expenditure of money or trouble, incomes far larger than an M.B. of London University, or an M.R.C.S. can hope to acquire for several years.

How far the medical profession is right in handing over to, medically speaking, uneducated hands the practice of the art of massage is a question I do not care to discuss, but it is an open fact that highly qualified medical men all over London can be obtained for one-fourth of the sum that a better-class *masseuse* charges for a visit, and for discharging a duty certainly not more laborious or distasteful than, if as much so, as many of those obligatory on the medical practitioner.

Let us dispassionately and without prejudice consider how far massage is useful in gynæcological practice. In doing so I would ask you to enlarge your view of the "study of a woman" from the limited mental horoscope bounded by the ovaries and broad ligaments, and embrace in your contemplation some of those associated conditions which this study forces us to include. Permit me to illustrate my meaning by touching here lightly on the outlines of a case, which it is my intention, through its extreme interest from some points of view, to publish *in extenso* at a future time.

A lady consulted me about three years since. From the date of her previous confinement, three years before this, she had suffered from constant headache, the pain occasionally being of an excruciating nature. She had never, she said, been a single day without it. There was also present violent periodical menorrhagia. She was a most intelligent woman, and was by no means what would be described as of a neurotic temperament. She had been to several physicians. She had tried a number of remedies, including a hydropathic course, and had gone for change of air a few times. The bowels for some time were only relieved by enema. On examination I found a large completely-retroverted womb. I examined both her teeth and eyes for other causes of reflex headache. I discovered that she had a hypermetropic astigmatism of less than a dioptric, though she had an artificially-induced myopia from spasm of accomodation. All her imperfect teeth had been stopped, and she did not complain on percussion of any of them. Suffice it to say that this lady has been, on and off, under my care for the past three years, and that though her astigmatism was completely met and the uterine condition cured, the vertex headache persisted to the latter part of the past year. I may remark that amongst other remedies I tried the constant current, Charcot's metal discs, and a course of massage, all to no purpose. Again, eighteen months since, I had all the teeth overhauled without any result. Last year the teeth again began to pain. She had them attended to by a local dentist, and shortly after came to London for a course of head massage. Without going into details I may say that this visit resulted in the extraction of eleven teeth from the upper jaw, by Mr. Baly, of Harley Street, the discovery of exostosis and partial obliteration of the dental nerve canal in several of the teeth, and subsequent complete cure of the headache. The lady is now in the fourth month of pregnancy. I think this case teaches its own lessons without observation.

I may divide the consideration of this subject thus: first, I must make some necessarily brief and condensed observations on the physiological action of massage, and secondly, discuss how far these explain the therapeutical application of the art, and finally apply these facts to the practice of the gynæcologist.

I wish, however, to state that these observations bear more particularly on massage in which the patient is passive, including the labile interferences, either with the hands of the operator (beyond question preferable), or with rollers or muscle beaters, such as those of Klemm, used by some. Though it must be remembered that the calisthenic exercises and mechanical aids of what is popularly known as "the Swedish cure," and commonly associated with the name of Ling, can not be dispensed with in many cases. I allude to those cases in which we desire to avail of this method of localising and grouping muscular resistance and movements in associated action by more energetic and betrer distributed force than we can obtain by manual manipulation. Such cases, for instance, are those of muscle disuse, following injuries, atrophic tendencies after paretic states, muscle deformities, as in the various talipes, articular malpositions due to neuromimesis, injury, adhesion or muscular action; scoliosis; rheumatic sequences in joints.

There is then a second group of cases in which such mechanico-therapeutical means are invaluable—viz., patients of the neurotic type, often with indolent, phlegmatic, hypochondriacal temperaments, this includes the costive, fanciful, capricious, tea-drinking, romance reading, morbidly introspective class of woman—full of self. What is left of mental exercise resolves itself mainly into a game of shuttlecock between her stomach and her ovary. A little diversity in this amusement is invaluable, and she gets it in the periodically imposed calisthenics. Some of the energy, resolved into fat, is restored, or that lost to enervated brain and muscle-nerve is regenerated.

I cannot delay to analyse and compare the effects of the different kneadings, frictions, strokings, tappings or

beatings, known as pétrissage, friction, effleurage, tapotement. I must group these various methods of action under the general term massage, and even include with these manipulations certain flexions and extensions or movements that are of necessity often combined with them in practising massage. Yet the physiological fact must be remembered that the nature of the stimulus—its character and mode of application, applied to a muscle, influences not alone the kinetic energy of the muscle, but also the force and distribution of the reflex impulses. We do not get the same results with stroking, as we do with either vibration movement or tapotement.

With deep kneading we have a different result from that obtained from both of the former acts. Let us summarise, albeit very imperfectly, the more important physiological effects of massage on muscle, nerve, vascular distribution and lymphatic supply.[1]

Muscles.—The chemical and physical changes consequent upon stimulation of muscles and muscle action, which modern physiological research has established. (*a*) Generation and discharge of carbonic acid; (*b*) Absorbtion of oxygen; (*c*) Creation of lactic acid and other chemical changes in the muscle; (*d*) Probable slight increase in muscle temperature; (*e*) Slight alteration in bulk of the muscle, attended by changes in the blood supply, both in quantity and character; (*f*) Generation of reflex impulses; with regard to this effect it has to be remembered, as Foster remarks, that "a muscle, even putting aside the visible terminations of the nerve, is fundamentally a muscle and a nerve besides;" (*g*) Readier response to electrical stimuli after massage and probable electrical changes, during massage excitation in the muscle nerves excited; (*h*) An influence on unstriated muscular peristalsis.

Nerves.—Chemico-physical molecular changes in the nerve tissue, starting both sensory and motor impulses; these centripetal impulses affect the central ganglia and influence both automatic and reflex actions. The phenomenon of inhibition is manifested. Analgesia is produced by prolonged and continued pressure.

The Vascular Mechanism.—The main effects are to be seen in the peripheral arterial resistance. The peripheral resistance is generally lessened (at times may be temporally increased) by massage. This is principally due to the following effects: altered nutrition of parts, change in the peripheral vaso-motor control; reflex stimulation of the vaso-motor centres; altered blood pressure due to the presence of carbonic acid and loss of oxygen (according to Sommerbrot,[2] intra-bronchial pressure taking an important part in this action on the heart). These effects are manifested in altered blood pressure and arterial tension, primary diminution, secondary increase.[3]

The heart's beats may be influenced by (*a*) the local reflex affects on the skin and muscle, or through the abdominal nerves, during abdominal massage, from splanchnic inhibitory action; (*b*) by the alteration in the arterial pressure, either local or general, brought about by the massage. Such vascular changes are necessarily attended by a local determination of blood, by alteration in the velocity of the blood current, in the metabolic tissue changes, in the nutrition of the part massèed, in the comparative rapidity of the removal of excrementitious material. More especially important are such physiological effects if manifested in the case of the portal and renal circulations.

Lymphatics.—In deep massage of the extremities, or kneading, the centripetal flow of lymph in the tendon and fascia lymph vascular space is expedited. This will be the case also in the tendinous and fascial structures composing a great part of the abdominal wall; the processes of absorption and resorption are promoted; lymphatic glandular activity is excited. The same occurs in the more superficial lymph vessels, from stroking the skin and vibration movements. During deep abdominal massage a powerful influence must be exerted on the lymphatic vascular mechanism, and on the nature of the fluid in the lacteal vessels. This will result directly from the continued or intermittent mechanical pressure exerted through the abdominal wall, independently of the altered relations between the superficial and deep lymph currents and the blood vessels. It must also follow from the effects of massage on the portal circulation. I allude to the more rapid reception by the portal blood, of the products of digestion, which find their way into it. This temporary increased diversion of food elements necessarily influences the chyle and the tension of the lacteal vessels. Also in general massage, followed by abdominal, through the continued suction effects of increased respiratory movements and general (primary) diminished venous pressure the lymphatic flow is temporarily encouraged, while through the nervous influence on the abdominal vascular system generally, lymphatic absorption is promoted.

These physiological facts, necessarily modified by the local anatomical relationships, can be well applied to the pelvic structures in which we, as gynæcologists, are more especially interested.

We may correlate such physiological effects of massage with the more manifest physiological phenomena and effects noticed in its practice. In order that I may save time, I arrange these latter in tabular form.

1. Slight immediate changes in body temperature, these are not constant and vary with rare exceptions to the extent of a degree more or less, of this I have satisfied myself several times. There is occasionally a fall—this is not so common as a slight rise.

2. Decided increase as a rule in muscle nutrition and power of endurance, increase of muscle weight.

3. Restoration of reflex excitability in weakened muscles, and the improved association of reflex and automatic action.

4. Reduction of cutaneous and muscular hyperæsthesia, and relief of pain arising from reflected irritations in distant regions.

5. Increased effects of galvanism when used after massage, necessitating reduction in the strength of the current, and increased care in its employment.

6. Improved peristaltic action as shown in the case of the nonstriated abdominal muscles of the intestines, and the œsophageal muscles.

[1] *I desire to express my obligation mainly to the Classical Text-book of Professor Michael Foster in compiling this summary of the physiological results of the various experimental researches which bear on the effects of massage or gymnastic exercises. Also I have had, amongst other sources, special assistance from the excellent manual of Dr. Joseph Schreiber, translated by Dr. Mendelson, of New York (Young Pentland, Edin). Another admirable manual in the English language is the Practical Treatise on Massage, by Douglas Graham, of Boston (Wood & Co., New York).*

[2] Sommerbrot: ueber eine bisher nicht gekannte wichtige Einrichtung des merschlischen organismus. Tübingen, 1884.

[3] See Schreiber's "Manual of Treatment by Massage," translated by W. Mendelson, M.D.; page 88. New York.

7. Results of improved nerve changes, as we find in the case of muscle. These are shown in restored nerve function, in healthier brain action, in the production of sleep, in alleviation of perverted and distorted mental symptoms.

8. The improvement in the tone and character of the pulse under massage treatment; the good influence on a sluggish circulation, as exhibited in the effect on cold extremities; the same result in cases of rhythmic irregularity of heart due to torpid hepatic circulation, flatus and abdominal obesity. The occasional attack of syncope, which I have had in two instances, is the effect of either a reflex inhibitory stoppage of the heart's beat, or a syncope arising from rapidly lowered arterial pressure. In one patient, vascular and nervous excitement were so pronounced every time head massage was tried that I had to abandon it. This was shown in suffusion of the face and eyes, sense of weight in the head, great mental excitement, hysterical crying; these symptoms were followed by corresponding mental depression.

9. Absorption of fat, loss of weight due to the removal of excrementitious material and useless fat, improved digestive powers, such therapeutic use of massage must be continued with the enforcement of dietetic rules and avoidance of fat forming food.

On the February 11th, I ordered general massage for a lady weighing 15 stone, 1½lb., who suffered from cardiac rhythmic irregularity. In a fortnight she had lost six pounds, and up to this day—March 13th—9½lbs.

Urine.—Interesting in connection with this case is an urinary analysis (No. 1.), made for me of the patient's urine of that passed immediately previous to an hour and a quarter's massage, and of that passed immediately after the rubbing.

No. 1.

Urine.	Before Massage.	After Massage.
Reaction	Acidulous.	Acidulous.
Total Solids	p.c. 5.90.	p.c. 6.55.
,, Urea	,, 2.40.	,, 3.05.
,, Uric Acid	,, .03.	,, .06.
,, Acidity (Lactic and Phosphoric)	,, .43.	,, .51.
,, Chlorine as Chlorides	,, .52.	,, .37.
,, Sulphuric as Sulphate	,, .12.	,, .15.
,, Earthy Salts	,, .31.	,, .34.
,, Alkaline	,, 1.00.	,, 1.10.
,, Specific Gravity of Sample	,, 1021.	,, 1028.

No. 2.

Reaction	Acidulous.	Acidulous.
Total Solids	p.c. 6.10.	p.c. 6.30.
,, Urea	,, 2.55.	,, 3.05.
,, Uric Acid	,, .06.	,, .08.
,, Acidity (Lactic and Phosphoric)	not estimated.	Not estimated.
,, Chlorine as Chlorides	p.c. .62.	p.c. .74.
,, Sulphuric as Sulphate	,, .18.	,, .15.
,, Earthy Salts	not estimated.	Not estimated.
,, Alkaline	,,	,,
,, Specific Gravity of Sample	p.c. 1026.	p.c. 1027.

The analysis was made by Mr. Brownen, F.C.S. Side by side with this analysis is another made a day or so, before, of the urine in a similar case of fat reduction. In this latter case Mr. Brownen did not estimate the alkaline or earthy salts, as fermentation changes might have influenced these and the acidity, as the urine was kept for forty-eight hours previous to analysis.

10. Resorption of lymph effusion and various exudations; reduction of glandular hyperplasias. While thus enumerating the physiological effects of massage, as experienced under favourable conditions of temperament and physique, and aided frequently by other therapeutical means, such as galvanism or faradism, baths, medicinal agents, special dietary, it must be stated that the process is frequently attended by various exaggerated or unexpected results in some or all of the directions eumerated which completely contra-indicate its employment. Certainly it is not a course to be prescribed or recommended in a careless or cursory manner.

It should not be entrusted without skilled medical supervision, to the judgment of ignorant men and women, to measure its extent and duration. I understand that we have now in London fashionable massage institutions for men and women, where the consulting *masseuse* exacts, in the first instance, a fee for prescribing the nature of the massage to be followed, after submitting the patient to the form of an examination. There are rubbers who speak of glands as "knots" in muscles, of tendons as hard "cords," which they endeavour to "disperse;" who rub dislocations for "sprains," "varicose veins" for nerves, and "rub" alike, the abdomen of the pregnant and non-pregnant. They are above a knowledge of all such trifles as the origin or insertion of muscles, the course of the circulation, the presence of cardiac disease, the nature of an effusion, or the position of the abdominal viscera. Ask such an one if she understands massage, and she cheerfully answers in the affirmative. She "has rubbed several cases, for Dr. So-and-so, who were undergoing the Weir Mitchell plan." She "knows all about it." She "has had some grand cures." She generally speaks of "*her* patients" and "*her* cases."

The "Weir Mitchell" system of "making fat and blood" has not been productive of unmixed good. But one of the evils that have resulted from the exaggerated and impulsive praise it received on importation into this country, has been the manufacture of a host of these Brummagen pests of medicine, the so-called "medical rubbers." They form a sort of link between a medical Vivandière and Franc Tireuse—irregularly tolerated but not recognised. It is quite sufficient to give one of these certificated frauds your hand, and ask her how she would proceed to *masser* it, or practise passive resistance flexion and extension movements on your arm to detect the imposition. The art of massage is not easily acquired by any, never by some, and for most medical men to pretend to do anything like justice to a patient, or to acquire that instinctive sense of muscle resistive force, or the skill in making manipulations would be absurd.

But does it much matter? I made Pil Hydrargyri frequently, in my apprentice days. I do not know that this fact added to my knowledge of its therapeutic effects. I learned more of this later from seeing five grains of it once cause severe salivation. If we know the effects and the object of the form of manipulation we advise, it is sufficient, in most cases. This, I maintain, we should know. Massage of the ear and eye, for example, I hold should not be practised, save by the medical man, or until the latter has satisfied himself of the competency of the *masseur*.

Once for all, let me say, that the massage I am speaking of is *not* "Vicarious exercise." It is not because exercise and massage have some points in common that they are ignorantly to be spoken of as substitutes the one for the other. It is somewhat of the crow and blackbird relationship. Massage in some of its methods is a form of exercise, but exercise is not massage. Manual massage differs widely from exercise, gymnastic or other, in the nature of the

excitation; the power of its limitation to defined areas; the direct action on the blood vessels, lymphatics and nerves; the comparatively slight evolution of body heat; the passive attitude of the subject; the absence of the more complex actions of a reflex and automatic nature, with the associated cerebral inhibitory supervision, which are the necessary attendants on exercise. The more complicated, or the more finely adjusted such exercises, the more widely do they depart in their nature from the manipulations of massage. We might as well compare the necessary manipulations, physical labour and fatigue of the *masseuse* with the effects on the person massèed. Therapeutically we might expect to find massage of benefit in gynæcological practice, in the following affections.

1. Atonic conditions generally, both of muscles and nerves, as for instance, relaxed abdominal walls, intestinal flatulent distention, chronic tympanitic states, chronic constipation, those forms of general debility and lassitude complicating menorrhagia, subinvolution, and other chronic uterine affections.

2. In reflex neuroses arising from or complicating morbid states of the generative organs in women, so called cases of irritable spine, reflex headache, cases of "uterine lameness," neuro-mimesis of joints, torticollis.

3. In amenorrhœa and dysmenorrhœa, especially those cases associated with anæmia and chloræmia.

4. In neuralgias of the pelvic nerves, oophoria, neurasthenic coccygodynia.

5. In unhealthy fat accumulation.

6. In masturbators.

7. In that numerous class of female patients, in whom there is no organic disease, and that we group under the terms, hysteria, neurasthenia, hypochondria.

8. Glandular hyperplasia.

9. Mammary infiltrations, in chronic mammary hardening, in threatened milk coagulation, in mammary neuralgia.

Here I may casually refer in passing to the splendid results I have seen in chronic constipation from abdominal massage. I allude particularly to cases of fœcal accumulation. I believe the proper treatment for the more obstinate of such cases to be, dilatation of the sphincters, clearance of the rectum, followed by a course of galvanism and deep massage of the abdomen. Nearly three years since I pursued this course in a lady who came to me from Australia, who had not for four years had a natural motion. I saw her again last year. She had abandoned aperients. A course of belladonna and nux vomica should accompany the massage.

I have here purposely included only those affections in which I have had ample personal proofs of the benefit of massage. I do not in any observations I make refer to combined internal and external massage, of which there are as many kinds as there are methods of gynæcological examination. I do not think that such modes of treatment are likely to find favour in this country. How far a licensed abuse of this practice might be carried we need not discuss. How far the possible advantages would be overbalanced by the certain evils, it is not difficult to surmise. No—we have had enough of internal massage in the shape of unwarrantable, unnecessary, and unduly prolonged medical examinations, to desire to invest with the professional sanction of such an association as this, a new tribe of uterine and vaginal manipulators. I know nothing personally of this form of massage in metritis, ovarian tumour, parametritis, perimetritis, cystitis, uterine tumours. It is not probable that I shall ever resort to it in such cases. Not having tried its efficacy, I do not wish to criticise *the results* of those who have. Still, I cannot help thinking, for a variety of reasons, both as regards operator and patient, that the time might have been more beneficially spent in trying other therapeutic or operative measures.

It would seem superfluous to speak of the dangers attending the use of external massage in parametritis, and the risks of an uncertainty of diagnosis in these affections or to the situation and character of effusions, but in works on massage, its employment is advised by various authorities in these conditions. One thing appears certain, that the responsibility of administering it in acute pelvic cellular or peritoneal inflammations should rest with no one save a qualified medical manipulator.

Even in cases of chronic pelvic lymph or serous exudations, I maintain, no mere nurse should be entrusted with the administration of massage, and no one should advise it save a physician, and one well versed in such diseases. I have known patients who were "rubbed" while suffering from fibroid tumour and ovarian-cyst. The kinetic energy here might have been better expended on the lady's boots. Not long since I had a patient with contracted vulvar orifice, lupoid degeneration of the vaginal wall, uterine hœmorrhage. She consulted me for the hæmorrhage. This was stopped after a little time, and I left. The next I heard of her was that she was being rubbed. A lady friend recommended it, and a doctor sent the masseuse. She was being "cured." The last I heard of her was that she was seriously ill, and under the care of the doctor who sent the masseuse. I have reason to believe that at the time he never locally examined the case. Now this is the abuse of massage, the vulgar empiricism that I complain of. A word on the Weir Mitchell plan. I do not deny its efficacy. I have had too many proofs of this in cases of my own to do so. I do, however, mean emphatically to give it as my opinion that discrimination and care are required, both in recommending it and carrying it out. I do not dispute that it is a lucrative method of treatment to the overseeing physician, more especially if he can bargain for half the large *honorarium* beforehand—*R.M.D.* But to fatten women up, and especially young girls, somewhat as a Bey of Morocco would do, in subdued light and on the flesh of ortolons, only substituting the æsthetic surroundings of a west end bedroom or boudoir for the seraglio, milk diet for the food of the luscious bird, and massage for a species of "lomi-lomi," is not always so permanently conducive to health of mind and body as we are led to believe. In one particular case I am cognisant of, such a course was attended by disastrous mental results, the patient narrowly escaped a lunatic asylum.

You can no more separate mind and body, says Professor Bain, than you can bisect a man's intelligence. The enforced stuffing and isolation entailed in this modern method of making blood and fat, though after all, as I have hinted, not so very modern, are hardly the therapeutic means to blindly bargain about beforehand, as one would for a trip in a P. and O. Steamer to Suez and back. I say that while such isolation and mechanical management may answer in a certain proportion of cases, it is a matter of simple common sense (call it, with Professor Huxley, "common ignorance," if you will) that it cannot but be

followed by injurious results in others, while in many the improvement, at best, is but of a transitory character. Let me, however, cite, in proof of the benefit of the Weir Mitchell system, the outlines of one remarkable case. A young lady, of highly neurotic temperament, consulted me for œsphageal and spasmodic stricture; she suffered from dysmenorrhœa, and there was a slight degree of retroversion. She was greatly reduced. The retroversion was restored. Still the difficulty of swallowing continued, notwithstanding active local treatment, œsophageal galvanism internally and externally, the passage of the bougie, and various remedies in the shape of nerve tonics, bromides, etc. However, ultimately she recovered sufficiently to enjoy food and revert to her ordinary duties. Some months subsequently she returned worse than ever. She was greatly emaciated, and could with difficulty swallow even a teaspoonful of fluid; the swallowing of any liquid was attended by a loud gurgling. An atonic state of the muscular fibres resulted in a pouch-like dilatation of the gullet, in which liquid collected, and from which it regurgitated. The skin was dusky and the face pinched. Altogether her state was most wretched. Still, I could pass, with a little difficulty, a large œsophageal bougie into the stomach. Suffice it is to say, that with a six weeks' course of Weir Mitchell's plan, combined with massage of the neck muscles and external galvanism, this patient was perfectly and, I believe, permanently restored to health. She was isolated from friends for a period of about five weeks.

I will conclude with a summary of one instructive case. About four years since, a young lady, accomplished and well educated, injured herself in playing tennis. She was examined under chloroform, and a large ring pessary inserted. This was after a time removed, but not before it had caused vaginitis and some metritis. This was followed by various neurotic troubles, inability to walk, agonising ovarian pain, loss of flesh, general nervousness. Another consultation ended in the verdict of "shortening of the round ligaments." She came a long distance to London to me, in order, as she wrote beforehand, to have this done. I could find no necessity for the curtailment of the round ligaments, ; there were the remains of the metritis, some slight retroversion, intense vaginal irritation, catamenial irregularity and scantiness, some left Fallopian fulness and ovarian congestion. She was under my care for some time, and underwent a prolonged course of massage and modified Weir Mitchell regimen. The progress was slow. Gradually she recovered. Her circumstances were rather straightened. She wanted employment. Having intelligently watched the excellent masseuse who operated on her, for a considerable time, she determined to learn massage. She did so, got instruction, studied for herself, and is now a very successful masseuse. Needless to say, her round ligaments were not shortened.

I crave your pardon for the length of this communication. The importance of the subject is my excuse. No one can stand before you a more complete proof of the benefit of massage than the reader of this paper, whose shoulder-joints were so crippled after rheumatism, some eight years since, that his college gown had to be drawn over his shoulders before lecture for two sessions, yet who, after all remedies had failed, by the aid of massage, the Turkish bath, and galvanism, has twice since then rowed down the Thames from above Oxford to Hammersmith.

HEALTH RESORTS OF THE WORLD.

XXIX.—BOURNEMOUTH AND ITS NEIGHBOURHOOD.

By Alfred J. H. Crespi, of Wimborne.

Nothing, I venture to think, gives such a charm to the country as an abundance of trees, and the streets of Bournemouth are greatly favoured in this matter, in places resembling shady lanes. But to make a walk along country lanes thoroughly enjoyable, a good deal besides trees is necessary—the air must be clear and dry, the temperature warm, and the country itself interesting and well cultivated. Still, however warm and bright the day, and rich and verdant the meadows, the dearth of trees takes away more than half the enjoyment of a long stroll through country lanes. Sir Arthur Helps once wrote that the loveliest scenery failed to delight him unless the air was balmy and calm: he much valued too another great charm of country life, what the Romans would have called *susurrus*, the aggregate of many gentle movements of many gentle creatures.

There are regions of the world where the scenery is magnificent; and the eye never wearies of gazing upon boundless plains teeming with life, and grain, and fruit, or on distant ranges of snowcapt mountains, while here and there the landscape may be relieved by broad belts of dark-green woodland, or by glimpses of the distant sea. But though these objects impart beauty and variety to the scenery; though they raise the thoughts to Him, who called this wonderful world into existence; though they form a glorious picture—they may not necessarily, when the several parts are closely examined, be pretty and interesting. In other words, the landscape as a whole, when viewed from a distance, may be lovely, and the recollection may long fill the mind with pleasure; it may even be so beautiful that it might be impossible to conceive anything more exquisite, or to weary of drinking in its wonders. Yet in that extensive and varied panorama there may be no pretty, little-frequented lanes, no sequestered nooks, in which the lover of nature could gladly pass a few quiet hours. It may be distance alone which lends "Enchantment to the scene, and clothes the mountain in azure green." The most beautiful parts may lose their attractions as soon as entered and closely examined; the mountains, when climbed, may be bleak and barren; the forests, when explored, may be dull and gloomy; and the fields, when traversed, may be only wide tracts of badly-cultivated and uninteresting land. In more genial climates than ours, there are said to be cities which at a distance are resplendent in the warm rays of a cloudless sun, and seem invested with the fascinations of a fairy scene; and so the most magnificent scenery may be that gazed upon from a rugged peak in the midst of a wild and barren country. The traveller hastens to enter the white streets sparkling in the sunshine, and finds on nearer approach only squalid buildings, narrow, dirty lanes, and miserable people. Thus is it with many far-famed scenes which, from a distance, enchant the eye, but nearer at hand are found to be monotonous and unpleasing. It seems to me that though England has not a balmy and cloudless atmosphere, like that of more favoured regions, though her landscapes are less extensive, her plains often shrouded in mist, and her mountains less lofty, there is a

bewitching softness in her woods and lanes, in her fields and dales, elsewhere unsurpassed. This is the opinion of many cultured and thoughtful people—ardent lovers of nature—who have had frequent opportunities of seeing the far-famed beauties and marvels of lands, where the sun shines brighter and oftener, and the atmosphere is less humid. There they say, the hills, the forests and the dales are very beautiful; but they lack the peculiar loveliness of an English rural scene. It may be the love of their native country which has, in some cases, led to the formation of this opinion; but, however that be, is there anything more sublime, more peaceful, than an English landscape basking in the summer sun? I at least want to see nothing more soothing.

When the hedges, after their long winter sleep, begin to clothe themselves in their lovely spring dress, and the trees put on the garb of summer, when the days lengthen, and the sun shines with fervour, hundreds of English hamlets, thousands of English lanes could be found, where the most restless might be at peace, and the most troubled might find happiness. A few miles from those immense hives of population in which half a million men and women toil to earn their daily bread, day after day, summer and winter, in the midst of squalor and dirt, temptation and suffering, there are almost certain to be lanes and woods basking in the glorious sunshine, and merry with the song of birds. How beautiful are the fields in those parts of the country where they are one mass of golden tinted flowers! How lovely are the wild straggling hedgerows, covered from top to bottom with white hawthorn blossoms! How tranquil are the woods, in which fifty kinds of trees grow and give a variety to the foliage which never tires the eye! I do not say that the country is everywhere beautiful, nor that every village is charming; but there are in thousands of parishes beauties enough to make the heart thankful and the eye glad. In all probability, country lanes and fields are more deserted than formerly. At any rate, many high roads, along which we might now wander for hours scarcely meeting half a dozen persons except in or near villages and towns, were once the great national arteries, along which carts, coaches, and foot passengers flowed in a continuous stream to all parts of the land. Now all is changed. The railway has taken the place of the old road, and the latter is seldom trodden. There has also been a lamentable drifting of the population into the great cities and ports, and the rural districts are less traversed, less frequented, than they were fifty or even a hundred years ago. I have walked thousands of miles along grass-grown lanes and roads, and passed through hundreds of villages, even close to great towns, where the solitude was seldom disturbed by man. Last summer, I wandered for many hours, three or four evenings a week, through one of the most beautiful districts in England, and though never far from a town in which scores of thousands of mechanics ceaselessly toiled, I did not meet fifty people in the hundred miles I walked every week. Nay, once or twice in the course of a ramble lasting eight or nine hours, I did not see half a dozen persons. Men talk of the stony wilderness of London, where the weary outcast may find solitude which no one attempts to disturb; but a solitude far more soothing, and much more complete, might be found in many a thinly-peopled country parish. The outcast might there take possession of a barn or shed, and days would go by without anyone intruding on his sorrow. If I wanted to pass three or four hours perfectly undisturbed, I should go by train to the nearest country village, and then walk along any quiet lane for a mile or two, and by that time I should have left man and his belongings far away. The sun might rise high in the heavens, and sink again to rest, and had I chosen my quarters well for the day, not more than two or three persons would disturb me. There are parts of England, not many miles from the crowded town where I originally commenced this article, which give not a bad idea of the solitude of the backwoods of America and of the plains of Australia.

Thackeray, in "The Virginians," has beautifully described the change that has come over our country roads and lanes. He says: "The high road a hundred years ago was not that grass-grown desert of the present time, it was alive with constant travel and traffic; the country towns and inns swarmed with life and gaiety. The ponderous waggon, with its bells and plodding team; the light post coach that achieved the journey from the "White Hart," Salisbury, to the "Swan with Two Necks," London, in two days; the strings of pack horses that had not yet left the road; my lord's gilt post-chaise and six with the outriders galloping on ahead; the country squire's great coach and heavy Flanders mares; the farmers trotting to market, or the parson jolting to the cathedral town on Dumpling, his wife behind on the pillion—all these crowding sights and brisk people greeted the young traveller on his summer journey. Hodge, the farmer's boy, and Polly, the milkmaid, bobbed a curtsey as the chaise whirled over the pleasant village-green, and the white-headed children lifted their chubby faces and cheered. The church spires glistened with gold, the cottage gables glared in sunshine, the great elms murmured in summer, or cast purple shadows over the grass."

But to leave the glories of country rambles and come to the subject proper of my article. One of the most interesting events in the history of Bournemouth was the cutting of the new line from Brockenhurst to the East Station, a work involving great engineering difficulties, and costing three quarters of a million. For some years, the obstacles to success threatened to overwhelm the contractors and to wear out the patience of the residents in the town. At last the Directors were rewarded for their energy and perseverance, and the official opening of the Direct Bournemonth Railway, on the 5th March, 1888, to which I received an invitation to represent the medical profession, may be taken as a good text for an article on that rising watering place, which has lately been growing in favour, and is competing keenly with older towns over which it has many unquestionable advantages, the chief of these being its comparative newness. Some watering places, like Weymouth, were general favourites several generations ago, and the older parts are consequently narrow, crooked and unattractive; but that does not apply to Bournemouth, which has sprung up in the lifetime of people still young. Dr. Wake Smart, of Cranborne, tells me that he remembers the town when it consisted of only half a dozen houses, and when no expectation of its future importance had entered anyone's head. The roads are straight excellent, and broad, the side streets are wide and open, and the place has a picturesqueness rarely found in English towns. Moreover, the area covered is extensive, and the houses are solidly built, with usually ample space around them, so that the larger villas and lodging houses stand in shrubberies and small fields.

Guide books to the place of course abound, the most complete, perhaps, is the "Medical Aspects of Bournemouth," by Dr. Horace Dobell, a brother of S. Dobell, the poet, and

one of the many medical men, who, of late years have flocked into the town. I shall not speak with anything but respect of his book, which goes perhaps too much into medical details, and is somewhat disfigured by reports of over forty cases of illness; it must have cost him much labour. As I am a perfect stranger to him, and have never even seen him, I can speak with greater freedom. Dare I hint that many guide books are couched in rather too flattering terms. It is a pardonable weakness of the compilers of such works to know only one place, the one in which they reside. The first paragraph of almost every book of this description might commence something in this fashion: "In this beautiful place snow, fog, and mist are unknown, cold is never experienced, heat never troubles the visitor, rain only descends at night, and all the deaths are among strangers who have come to die, the residents being endowed with immortality." Dr. Horace Dobell at any rate does not hesitate to claim for Bournemouth the proud preeminence of having the most perfect and genial climate under the sun. This does strike the wanderer into many lands as going rather beyond the latitude allowed to the guide-book maker. And yet Bournemouth has conspicuous advantages of climate and position, and fewer people would leave it disappointed, were the descriptions that are published more in accordance with fact. But when people are told that at Bournemouth they will find a perfect climate, and that the sun always shines there, even on the coldest days, they cannot fail to be disappointed. Dr. Dobell actually talks of "the only very bad week of the whole year." as though in most winters good weather could be counted upon with as much regularity as daylight. Nowhere in the United Kingdom is the winter warm, agreeable and dry; nowhere can invalids hope to sit out day after day; wide differences certainly there are, and the southern and south-western districts have less cause to complain than those farther north. But whatever horrors fill our winter even at Bournemouth, our summer is widely different; it is delightfully free from the annoyances and insect pests of hot regions. If there is one wish which I might express with regard to it, it would be that it brought more fine, cloudless days; I do not ask for higher temperatures, though they would be welcome; I do not ask for a longer summer, though it is hard to have so few fine days till June comes, and not to be able to count on them after about the 20th of August. But I wish that, during the ten or twelve weeks, when the days are long, the flowers blooming, and the fields green, there were fewer clouds. I do in short wish that the glorious, merry sun would not so often hide himself behind dense clouds, and leave the earth to mourn his absence.

For a British health resort Bournemouth is greatly favoured, and has many attractions for people who cannot go abroad to winter; but with the rapid cheapening of continental travel, even our most fortunate health resorts feel foreign competition keenly. I shall lay before the reader some valuable tables of temperatures, and other climatological observations, from which he will see the exact position of the town and its neighbourhood. These figures convey volumes, and are worth all the rhapsodies and poetical descriptions with which professional showmen try to attract the public. At the official opening last year I was placed in a carriage with a great metropolitan luminary in front, by my side sat a leading Bournemouth doctor, who did not know me by sight, and so he totally ignored me, while he enlarged to the astonished and not very astute Londoner on the tropical glories of the climate. The day chanced to be singularly warm and soft, and in marked contrast to dozens that had immediately preceded it; but the veracious Bournemouth practitioner described it as exactly the kind to be always counted upon; "this is just a fair average day," he continued. "Bless my soul," ejaculated the astonished metropolitan physician, "we have in Town been having very cold weather," and so, though he did not know it, they had at Bournemouth too.

TABLE I.

EXTRACTED FROM MR. MARRIOTT'S TABLES.

	Absolute		Mean Temp.	Annual Range	Cloud	Rainy Days	Inches of Rain	Relative Humidity
	Max.	Min.						
1885.								
Alston	80.4	5.1	43.4	75.3	7.3	225	42.26	87
Cheadle	82.8	21.0	45.6	61.8	6.7	201	30.25	87

TABLE III.

COMPILED BY MR. WILLIAM MARRIOTT.

HOURS OF SUNLIGHT.		
	1885	1886
London	1018	1003
Southbourne	1523	1538
Buxton	983	679
Ventnor	1704	1683
Blackpool	1326	1239

From Dr. Dobell's last edition of his work, I take without apology the following additional figures which are practically common property. There is not an exact correspondence between them and those already quoted: they give Bournemouth a somewhat warmer, drier, and brighter climate than the official tables warrant, but the difference is not very marked.

Mean daily monthly maximum for eighteen years:

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
44.5	46.7	49.0	54.6	59.6	65.1	68.8	68.8	64.3	56.6	49.5	45.0

Mean daily minimum of each month:

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
35.8	38.0	37.1	40.9	44.4	50.4	54.2	54.3	50.8	45.0	39.0	36.1

Mean daily monthly range:

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
8.7	8.7	11.9	13.7	15.2	14.7	14.6	14.5	13.6	11.6	10.5	8.9

Adapted mean monthly temperature:

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
40.2	42.2	42.5	46.8	51.1	56.7	60.3	60.7	57.0	50.4	44.1	40.8

The mean temperature of the year, according to Mr. Glaisher's method, is 49.4.

The maximum temperature of the year was above 80° in eight years, and below 80° in ten; while in eighteen years a maximum of 82° was only twice exceeded—in 1868 and 1876.

Mean monthly amount of cloud, perfect clearness being represented by 0, and complete cloudiness by 10.

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
6.1	6.1	4.6	4.4	3.9	4.2	4.2	4.1	4.1	4.1	4.9	5.8

Mean monthly amount of humidity, or relative humidity (saturation 100):

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
86	88	81	78	76	76	77	77	78	83	85	86

Mean monthly rainfall:

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
3.20	2.50	1.80	1.96	1.68	1.85	2.30	2.34	2.94	3.23	3.09	3.01

Average number of days on which any rain fell:

Jan.	Feb.	Mar.	April	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.
17	16	12	12	12	11	13	12	14	16	14	16

Average number of days on which the wind blew during the year from the following quarters:

N.	N.E.	E.	S.E.	S.	S.W.	W.	N.W.	Calm.
39	50	26	28	26	70	68	49	9

Those tables, which have the authority of Mr. Glaisher, F.R.S., and of Mr. William Marriott, the able and accurate Assistant Secretary of the Royal Meteorological Society, cannot be disputed. I am sorry to have to say so, but they dispose by the iron logic of inexorable figures of countless papers and articles on the Sicilian beauty of the climate, and hardly bear out Dr. Horace Dobell's description of a Bournemouth winter. They show that Bournemouth enjoys a climate three degrees warmer than Wolverhampton, with about the same absolute range of temperature, and the same number of rainy days, and not quite such a low absolute minimum. The one matter—and a very important one, too—in which Bournemouth surpasses the midland towns is in the greatly larger amount of sunlight; in other words, it has twice as many hours of brilliant sunshine as Buxton, Cheadle, or Wolverhampton; and, consequently, on many days, when it is not tempting to go out of doors in those places, at Bournemouth open-air exercise is agreeable, or, at any rate, endurable. But the climate is very far from perfect, and I cannot forgive the frequent and searching winds and the driving gales, which are far worse than those in sheltered midland districts. The biting sharpness of the east winds at Bournemouth—a disagreeable feature of the climate of the whole south coast from Brighton to Penzance—may fairly be set against the small amount of fog experienced near the sea. I do not want to be captious, but few invalids from a distance go to Bournemouth, or, indeed, to any other southern watering-place, without complaining that they have been deceived. Let them remember that the climate of the United Kingdom is remarkable for its equability, that ocean breezes pretty equally modify it in all districts, and that between the extreme south of England and the most northerly of the Scotch islands the difference of mean temperature for the year is barely six degrees. Contrary to the impression sometimes entertained, however, July in the south—over a small area between Bath, London, Oxford, and Salisbury to be exact—is 11° Fahr. higher than July in Unst, while the difference in the January temperatures between the two is scarcely appreciable. From the beginning of November to the end of March longitude, not latitude, is the most important factor. Still, the winter of the south coast, though so little warmer, is far brighter and pleasanter, and that is a distinct gain.

Bournemouth is the name given to a large and somewhat ill-defined area, covered more or less thickly with houses. The western portion is called Parkstone, and is in the parish of Poole. Then comes a long, narrow district of houses—Branksome, Bournemouth West, and Bournemouth East, and still further to the east, Boscombe: indeed, from Poole to Christchurch, a distance of nearly nine miles, there is a good deal of scattered building, which every year is filling up fast, and stretching northwards. Bournemouth is not at present incorporated, although it ought to be; and it is impossible to speak with certainty as to the population: 30,000 is the figure often given, but surely this must include Poole and Christchurch. The main portion of Bournemouth is curiously shaped; it is long and narrow, and extends full three miles along the Old Christchurch-road—a straight and very handsome thoroughfare. The town, unlike many other seaside watering-places, is not exactly on, but at a distance of half a mile or so from the sea, at certain points approaching nearer, and at others lying farther off. From no part of the town, properly so called, can the water be seen, although a few houses on the east and south cliffs look down on the beach, with its bustling crowds and its magnificent pier, and much of the attraction of the place is actually due to its not being on the sea, so that there has been more space for new houses and roads than there would have been had the town only been the expansion of an old fishing village. There is no road along the sea, though several lead down to it, and some of the chines and ravines are very beautiful. No stately terrace or crescent looks over the water, and in this respect the contrast between Bournemouth and some other watering-places is curious and decided, and the stranger finds all the charm of novelty.

Bournemouth is singularly favoured; indeed, I do not know any other health resort that compares with it in the cheapness and endless variety of its sea excursions. Without a harbour, without shelter, it would seem to be the very last town to have such unrivalled advantages; but then, only four miles off is the capacious and convenient harbour of Poole, and from early in the morning till late at night steamers ply from Bournemouth pier to Yarmouth, the Needles, Ryde, Ventnor, Cowes, Swanage, Torquay, and—but more rarely—to the French coast. A guinea ticket entitles the holder to all the shorter excursions for the season.

Another feature is the churches, which seem far in excess of the requirements of the scanty population, and in their superabundance it resembles Torquay and Brighton. The services are usually ornate and frequent, though the attendance, except on special occasions, when the whole population appears to be present, is often small. Only St. Peter's has any great architectural pretensions, and it is one of the finest ecclesiastical buildings in the diocese; it is striking from its size, lofty and graceful spire, and abundant handsome ornamentation. A large and handsome Presbyterian Chapel has recently been built, and has a crowded congregation.

The place is not easy to describe: with no central railway station, with scarcely any centre, like an inland town, from which to start, and with few salient features, it does not easily lend itself to the requirements of the descriptive writer. It is somewhat lacking in striking natural advantages, as, for example, it has no Derwent Parade like Matlock, no splendid Promenade, Park and Pitville Gardens like Cheltenham, no Jephson Gardens like Leamington, and

no Pulteney-street and Royal Crescent like Bath. But it can do without these and other attractions, for it is a singularly handsome, clean, well-built, improving place, with light, sandy soil, quickly drying after rain, many imposing shops, and hundred of fine villas, to which constant additions are being made. Its pine woods, however, have long been its special feature. The soil being dry and sandy is not remarkable for its deciduous timber, but pines grow splendidly, and many of the streets, especially on the east cliff, are well shaded and extremely pretty, and in places, where the builders have not been too energetically at work, glens and chines are to be found that present a strikingly pretty appearance, totally unlike anything else which I have ever seen in a town, so that practically the place is unique. The Talbot Woods are said to contain one million pine trees. The rhododendrons, too, in June are very fine, and the display of flowers magnificent. Branksome Chine is especially famous for its rich luxuriance at that pleasant season, and so is the park near Herne Station, which then attracts crowds of visitors. In another respect Bournemouth is remarkable: it is in the long, narrow, well cared for public gardens, stretching for a couple of miles along a little stream to the sea. These gardens are crossed by the main road, not far from the Arcade, near the foot of Richmond Hill, and are as attractive as many a more pretentious park. On summer evenings crowds of excursionists wander along them and make their way to the pier to which they lead. From the foot, too, of Richmond Hill the outlook is very beautiful, and the visitors from the north cannot help being charmed, although they must not expect that the sun is always shining and the wind always still.

The town abounds in hotels, lodging and boarding-houses, and doctors; the last have swooped upon it like vultures. Some of the latest estimates give over sixty medical men in active practice among perhaps 20,000 or 25,000 people, a proportion reminding one of Leamington, Cheltenham, and Scarborough. One might consequently fear that the district was unhealthy, but never was there a greater mistake, for there is considerably less sickness, and the death rate is lower than in most places of equal population. One can only charitably hope that when the town becomes a second Brighton, if more doctors have not in the meantime come to share in the spoil, the patient and long tried medicoes, who survive the disappointments of years, will reap their reward. Complaints have been rife as to the exorbitant charges for lodgings, and some visitors have had good cause to wince. It is inexcusable that charges should be so high. At ordinary times hundreds of rooms are to let, and lodging-house keepers are persistent in their complaints that the place is empty. As there is no palatial terrace facing the sea, and no broad and magnificent promenade, attracting the richer visitors and fixing the local tariff, no part of the town should demand high rents, and one can only regret the imprudence of the lodging-house keepers, which drives many visitors away.

Amusements are not on the whole very varied, nor of a high order. The theatre, which used to be one of the prettiest and most tastefully arranged I have ever seen, has recently been converted into a nondescript kind of hall for miscellaneous entertainments; and unfortunately, in the transformation, its special fitness for the drama has been sacrificed: still there are frequent concerts of the highest class, and the local temperance societies are in a chronic state of unrest, and are eternally arranging special missions on a large scale.

Of land excursions the variety is fairly large, but not close to the town. The two favourites are Wimborne, famous for its magnificent and unique Minster, with its great central and west towers and Chain Library, and the New Forest. During the summer carriages full of excursionists ply many times a day to Wimborne and to Rufus's Stone; the latter is twenty miles from the middle of Bournemouth. But the most beautiful country, Kingston Lacy and Badbury Rings, the far-famed Park and White Farm of Crichel, the Castle Hill at Cranborne, and the superb Museum at Rushmore, could not from their distance be conveniently reached except from Wimborne, between which and Bournemouth there are fifteen trains up, and as many down, a day. Christchurch Priory is also very grand, and in size, massiveness, and interest has no rival nearer than Salisbury Cathedral and Romsey Abbey; the last is not easy to reach from Bournemouth, though it well repays a visit and a critical examination and its splendid proportions and heavy Norman architecture make an impression never effaced: every one who could get so far should make the most of his opportunity.

But Bournemouth is a health-resort; for what diseases is it good, when is it in season, and who should go there? Enquiries are readily and encouragingly answered; it is always in season and good in all complaints, and in truth some visitors are always there, and invalids afflicted with every complaint under the sun are welcome. Although described as a winter resort it is, like all seaside places, pre-eminently a summer favourite. Easter and Whitsuntide, if mild, bring a good many excursionists and visitors for a few days, then there is a lull. June sees a little stir, while in July it is often full, but in August and September it is crowded, and were the charges more reasonable all the lodgings would be occupied; true Dr. Dobell says that all the rooms are at times let, even in winter, but my experience differs from his, and I am no stranger to the place. In winter the place is very far from full; there are then, of course, no land or sea excursions in spite of the tropical sunshine, and not many amusements, compared with those of large towns that is, and invalids do not come in large numbers. Moreover, imprudent mis-statements as to the climate disappoint most people who venture so far in winter. It is hardly wise to call a place the English Nice or Mentone; it makes strangers expect so much, and to promise exemption from cold and other climatic disagreeables is still less prudent. With March the weather often becomes bright, and short fine spells may be expected; these increase in length and frequency through April, and from the early part of May to the middle of August there are few grounds of complaint. The autumn, after the break up of the weather early in October, is often dull and wet, with frequent mild, soft, humid days, on which exercise is pleasant enough—foxy days, sailors call them the precursors of gales of rain and wind, and at Bournemouth these gales, when they do come, are felt with a vengeance, as I can testify; still the invalid can console himself with the reflection that in no other part of the United Kingdom is the weather likely to be pleasanter.

To sum up—Bournemouth is a charming town, rapidly growing in well-deserved popularity and favour, rather handicapped by the infrequency of the trains on the Somerset and Dorset; indeed, there are only three good trains to Bournemouth in the afternoon on that line, and not one in the morning, while from West Bournemouth only three good trains run in the morning to the North, and not

one in the afternoon. It is annoying to find that one has to leave Bristol at 6.20 a.m. to reach Bournemouth at 11.15. But were the trains punctual in getting in one need not complain so much, but unfortunately they usually keep very bad time, and are much later —five hours to do sixty-four miles or so, while one cannot leave Bournemouth in the afternoon for Bristol or Bath by any train that travels at good speed, four or five hours being again required. Much is expected of the Direct Bournemouth Railway from Brockenhurst to the East Station, which avoids the great detour at Ringwood, and the bad road from that quaint old town to Bournemouth. Should the new loop be well worked it will enormously increase the advantages of the town, and attract more visitors from the North and from London, and up to the present not many complaints are heard. Other much needed improvements are the doubling of the whole of the Somerset and Dorset System, and readier access to the North, with fewer delays at Bath and Templecombe, more amusements of a high order, and a pretty little theatre confined to the drama. Visitors must not be regarded as mines of wealth, as most of them are only just able to pay their way with economy. The rich few are everywhere welcome, but it is the struggling millions whom Bournemouth must do its best to welcome and provide for, and who would fill her coffers and enlarge her boundaries, although they might not be able to pay two guinea fees for a visit, and might not employ half a dozen physicians apiece.

XXX.—AJACCIO.

By an Old Oxonian.

A climate, in which the visitor may, for weeks together, have not one day of rain, cloud or wind, in which the nights are warm but not oppressive, and in which the spring temperature is absolutely perfect, makes the Englishman wonder if he has heard aright. We have small belief in perfect climates; for warm winters often mean burning summers; low latitudes are made unbearable by myriads of insect pests, noxious complaints, and intense and long continued heat, while high latitudes are usually distinguished by intensely cold winters, and much cloud. And yet, if all one hears is true, at last an Eldorado has presented itself in the shape of Ajaccio in Corsica. The visitor to the Riviera, looking to the South on a winter morning at sunrise, may see the sun appearing from behind some far away mountain peaks, so remote that they are seldom visible even under the most favourable conditions. As the day advances the peaks are lost to sight, and it may be some days or weeks before the fairy spectacle is seen again.

The charms of winter on the Riviera need no description; the warm, health-giving sun, the transparent atmosphere, the twenty fine days a month in the middle of winter, the luxuriant vegetation, and the bright coloured flowers combine to make a long residence a delight the memory of which never fades away. Drawbacks there are it is true—the chilly evenings hardly made endurable by the miserable wood fire, the keen mistral, the lack of those familiar comforts within the reach of all in England except the poorest, and the occasional spells of bad weather.

Ajaccio, however, is asserted to escape many of the disadvantages, such as they are, of the Riviera. Its magnificent position on the west coast of the picturesque island of Corsica is, once seen, never forgotten, while the placid Mediterranean, the deep blue sky and the majestic scenery in the background are attractions that more than recoup the visitor for any trifling inconvenience he may have passed through to reach the birthplace of Napoleon.

Corsica has been much improved of late as a place of residence; the steam communication is better, admirable roads encircle the island, and some cross roads have been cut, one, for instance, from Bastia to Ajaccio; life and property are both as secure as in England and the hotel accommodation, which not long ago, was execrable, soon promises to be excellent, and strenuous exertions are being made to build a large and commodious hotel on English principles and under English management, and as some of the promoters have a high reputation, and Corsica possesses advantages that few places in so high a northern latitude can equal, there ought to be a grand future before the island.

Of the history of Corsica we will say little, though it would furnish material for a long dissertation. The scholar remembers that Seneca passed eight years of discontented exile in Corsica, and every school boy knows that Pasquale Paoli, the patriot, and Napoleon, the daring conqueror of Europe, were natives of the island, and to the end of time Ajaccio will call up memories of such a character that we pray the world will never have a repetition of them.

Corsica is fortunate in situation and in configuration—situated in the middle of the warm and sunny Mediterranean it is protected from cold blasts from the North, and what that means we will proceed to show. In the middle of January, Nice is mild and pleasant enough, and the mean minima range from 38.6°F. to 42°F., while at nine p.m. the thermometer will mark 42° or 43°F. We need hardly say that though these figures are not higher than in sheltered places on the South and South-West coasts of England, the Riviera winter night is pleasanter and exposure is more agreeable; still the temperature is low, though very unlike that of cold spells in England, and of the Midland and Northern districts at that season. At Ajaccio, however, the difference is startling, and there the day maxima are 6°F. above those of Nice and Mentone, while the mean temperature of the month is from 4° to 6° higher and the nine p.m., reading is 10° or even 11°F. higher than at Nice. On an ordinary January night it is perfectly possible to sit out in the open air without any greatcoat, and to have nights so cloudless and moonlight so brilliant that the stay-at-home Englishmen can hardly form any conception of them. We remember looking down over a great continental city on a lovely June day last year; beneath us stretched for miles the sharp cut outlines of the broad and busy streets; we could distinctly see the leaves waving, while the mortar between the paving stones and the distant church steeples stood out clear and sharp as we should never see them at the same distance in England. The following evening, at six o'clock, we stood in London, in front of Charing Cross Station; the haze made objects a hundred yards off indistinct, and even on the opposite side of the not too wide street there was a mistiness that made us think longingly of the more favoured city we had so recently left. And once, some years earlier, we were walking in a Virginian City on a November evening, the scenery was not particularly majestic and the historical associations were possibly commonplace enough, but the genial warmth, the bright sunlight, and the tranquility made us wonder whether it could be possible that at that season English towns were dark and gloomy and outdoor exercise for pleasure hardly

to be thought of. Perhaps nothing more impresses the wanderer from England than the sunlight, the warmth and the transparency of a southern latitude, more particularly in winter, when the weather in almost every part of the United Kingdom is simply detestable.

Every year the facilities for getting away from home in the winter are increasing; travelling is becoming cheaper, easier and more rapid; places hitherto inaccessible are no longer difficult to approach or leave; English residents are to be found everywhere; English built and English managed hotels are springing up in parts of the world that were hardly known by name to ordinary Englishmen ten years ago, and Corsica seems likely to become a favourite residence, more particularly during the winter. Much of Corsica, moreover, stands at such an elevation above the sea that summer residence would have great charms; at the same time it is not so much the actual cold, measured by degrees, as the damp, depressing gloom of our Northern winter that makes so many people leave England for the South, and it is just at that season that, unless we are greatly mistaken, Corsica and more particularly Ajaccio will be found so attractive. At present, moreover, while to pass a winter on the Riviera, at Naples or at Malta hardly confers any social distinction, Corsica is still a *terra incognita*, and for some years it will be something to boast of having wintered in a land so near and yet so little known, so singularly favoured by nature and not altogether forgotten by art, and having some of the advantages of modern civilisation.

REFORM AT THE ROYAL COLLEGE SURGEONS OF ENGLAND.

The high-handed action of the President and Council of the Royal College of Surgeons in forbidding, and, with the aid of police, preventing its members from using their own premises, has stirred up an agitation which promises to put an end to the reign which has too long existed at this College.

The members, backed by a number of independent fellows, have started on the war-path, and so far they have won in the Law Courts. We submit to our readers the following Bill, and ask them to well consider it and support it by means of their local M.P's. :

DRAFT BILL TO AMEND THE CONSTITUTION OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND, AND TO DECLARE AND EXTEND THE RIGHTS OF MEMBERS THEREOF.

Whereas the Royal College of Surgeons of England is an ancient free Corporation, which has existed as a Society, Guild, Company, or Fraternity of persons practising Surgery under various names from very early times by virtue of several Royal Letters Patents and Acts of Parliament; and whereas it is expedient to declare and regulate the ancient rights of the Members of the Royal College of Surgeons of England, and to amend the constitution thereof, and to provide certain new regulations relating to the government thereof in lieu of and in addition to those now provided by Letters Patent and Acts of Parliament relating to the same, and to amend and alter certain by-laws :

Be it enacted by the Queen's Most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal and Commons in the present Parliament assembled, and by the authority of the same, as follows :—

1. At the next and every succeeding election of members of the Council of the College, the persons elected shall hold office for three years only, but shall thereafter be eligible for re-election subject as hereinafter provided.

2. From and after the passing of the Act, the Presidents and Vice-Presidents of the College shall be elected in manner hereinafter provided, and shall hold office for one year only, but shall be re-eligible, provided that the term of office of any of them shall not exceed three years consecutively.

3. Whereas it was part of the ancient constitution of the College and Corporation that all the Members thereof were eligible to the offices of Masters and Governors thereof, be it declared and enacted that from and after the passing of this Act it shall at any such election of a President or Vice-President be lawful to nominate as a candidate any Member of the College duly registered as hereinafter provided who shall on the day of election be of more than twenty years' standing as a Member of the College.

4. Whereas by the ancient constitution of the said College and Corporation all the Members thereof were in right of their membership entitled to meet together for their common affairs, and to attend and vote at the customary annual meeting, and at all other general meeting of their said Society; whereas by reason of the partial disuse of some of the said rights questions have arisen thereon which it is expedient to determine by the authority of Parliament; and whereas certain regulations and by-laws have been made in the premises which it is expedient to alter and amend, be it declared and enacted that on and after the passing of this Act the Members of the College are and shall be entitled to meet together within the hall of their College or elsewhere, at all reasonable times, for the consideration of the affairs of the College, and to propose resolutions and to vote thereon at every general meeting of the College, and to vote at any election of Presidents, Vice-Presidents, and members of the Council of the College (subject as hereinafter provided), and at any meeting to appoint committees for special purposes, and to adjourn any meeting to another place and time, and it shall not be deemed to be necessary to obtain the previous permission of the President and Council for the holding of any such meeting, or for the proposal of any business therein.

5. It shall be the duty of the Council to call a general meeting of the Members at least twice in each year, and to call at any time a special general meeting within one calendar mouth after the receipt of a requisition signed by twenty Members of the College; and if any special business be named in any such requisition, notice thereof shall be included in the advertisement convening any such meeting.

6. At all meetings of the Members of the College the President shall be entitled to take the chair, and the Chairman shall take the sense of the meeting upon all resolutions proposed by any Member of the College after three days notice in writing, and upon all proper amendments thereof.

7. Section XVII of the by-laws of the College is hereby repealed, and whereas doubts have arisen as to the validity thereof, it is further hereby enacted that it shall not be lawfully for the President or Council of the College to take or continue any action against any Member of the College for any alleged infringment thereof, or to continue or enforce any penalties or liabilities which before the date of the passing of this Act may be declared, or imposed, or attempted to be imposed, in respect of or arising out of any past alleged infringement thereof.

8. If any resolution relating to the expenditure of the revenues of the College is passed at any general meeting of the Members, by a majority of two thirds of the Members present and voting, the said resolution shall forthwith be binding on the Council and on any Finance Committee thereof; and any subsequent expenditure in contravention thereof shall be disallowed on any subsequent audit.

9. If, and when, the Council shall deem it desirable to incur any extraordinary expenditure to the amount of £1,000 or upwards, the President shall forthwith convene a meeting of the Members of the College, and shall take the sense of the said meeting on the said proposed expenditure; and no resolution of the Council sanctioning the same shall be valid unless or until the same resolution shall have been ratified by a meeting of the Members of the College.

10. The College Hall and Museum, and all other lands and hereditaments, and all the property whatsoever the said College is or may be possessed, are and shall be deemed to be vested in the President or Council in trust for the Members of the College.

11. No such meeting of the Members of the College, as hereinbefore mentioned, shall be entitled to alter the subjects or standards of any examination which the College is empowered to conduct, or to review any judicial act of the Council relating to the professional misconduct of any Member of the College.

12. The accounts of the receipts and expenditure of the College shall be open to the inspection of any Member of the College at all reasonable times.

13. A proper balance sheet shall be prepared by the Council in the month of October in each year, and shall be audited by an independent auditor, and published to the Members of the College on or before the first day of November, and the said published balance sheet shall be authenticated by the signatures of the President and Auditor.

14. An annual meeting of the Members of the College shall be convened in the month of November in each year, to which the annual report of the Council and the published balance shall be submitted.

15. No formula for a by-law or for the alteration of any existing by-law shall be finally passed and ordained by the Council until the same shall have been submitted to a meeting of the Members of the College after due notice thereof, and approved by them.

16. At the next and every succeeding election to fill any vacancy in the Council of the College, any Member of the College shall be eligible to be nominated as hereinafter provided, on the same condition as to the standing necessary for eligibility for election as a Member of the Council shall be subject to be altered from time to time by by-law.

17. No Member of the College shall be disqualified from holding any office in the College by reason only of his not being a Fellow of the College.

18. No Member of the College shall exercise the right of voting at any election of a President, Vice-Presidents, or member of the Council of the College, unless or until he shall be duly registered on the Electoral Register of the College for the time being, in manner hereinafter provided.

19. From and after the passing of this Act, the Secretary of the College shall act as Registrar for the purposes of all elections in the said College, and it shall be a part of his duty to make and correct an Electoral Register of the College in manner hereinafter provided.

20. As soon as may be after the passing of the Act he shall prepare and publish a revised addition of the "Alphabetical Register of the Fellows," and "List of Members," contained in the last Calendar of the College, in which he shall insert in one list the names, present addresses and dates of admission of all the Fellows and Members in such calendar mentioned in alphabetical order, with the following exceptions:—

1. All persons as to whom he shall be satisfied that they are dead, or that they have ceased to be Members of the College.
2. All persons as to whom it shall appear that they have no permanent address in the United Kingdom.
3. All Members not being Fellows who have been admitted to membership since the first of June 18 .

21. As soon as may be, the said revised edition shall be published in the College Hall, and in the *London Gazette*, and in two medical papers, together with a supplementary list of the persons whose names have been omitted on any of the grounds hereinbefore mentioned, and a notice that if any of the persons have been erroneously omitted, they are required to claim personally or by letter that their names should be reinstated within one calendar month.

22. After the lapse of the limited time the Registrar shall embody all necessary corrections forwarded to him in a final copy of the Electoral Register, and shall publish the same in manner aforesaid, as being the Electoral Register of the College for the year 1890, and the same shall thereafter be the Register in force at the annual or any other election until the first of January, 1891.

23. The Registrar shall, not later than May 15th in each succeeding year thereafter, publish a notice in manner aforesaid requiring all persons claiming to be registered, or objecting to any entry in the Electoral Register of the College, to lodge a written notice with him within one calendar month, together with such proof as the Council shall from time to time direct by by-law; but it shall be his duty, without any special notice, to insert in the next following Electoral Register the names of all Members and Fellows admitted during the twelve months next following the said June 1st, 18 , and so in each succeeding year.

24. If the Registrar is not satisfied as to the matters contained in any such notice he shall forthwith inform the claimant by registered letter that his claim is not admitted, and the claimant shall thereupon be entitled to appeal to the Council, whose decision shall be final.

25. The Registrar shall in like manner publish a list in each year of all persons entered on the then existing Electoral Register whom he believes to be dead or to have ceased to be Members of the College, or to have ceased to have an address in the United Kingdom, together with a notice that the names of the said persons will be omitted from the next following Electoral Register unless a claim is lodged by them in manner aforesaid, and the Registrar shall so soon as may be thereafter cause the revised Electoral Register to be published as the Register in force for the year ensuing.

26. The entry of any Member's name upon the current Electoral Register shall be conclusive of his right to vote at any election during the period to which that Register applies, which shall be from January 1st in each year till January 1st following, unless he shall have ceased to be a Member of the College.

27. From and after the passing of this Act all elections for vacancies in the Council of the said College, or for the office of President or Vice-President thereof, shall take place upon the first Thursday in July of each year.

28. At the next and all future elections of a President or Vice-President of a College, the same shall be elected by a majority of the votes of all persons who shall be then entitled under the provisions of this Act to vote in the election of Members of the Council of the College, and shall be duly registered as herein provided.

29. No Member of the Council of the College who shall be elected after the passing of this Act shall be liable to pay any fees upon or by reason of his election.

30. The Council shall in each year, at least thirty days before the said annual day of election, publish in the *London Gazette* and in two medical papers a notice of the forthcoming election and of the number of vacancies to be filled up.

31. Any member who is desirous of nominating a fit person at any such election to be a President or Vice-President or Member of the Council of the College, shall deliver to the Secretary of the College within ten days after the date of the publication of such notice a nomination paper in the form provided by the Schedule hereto, or as near as may be, containing the name and description of the person to be nominated for one of the said vacancies and signed by the Member nominating the said person and by three other Members of the College, duly registered in manner herein provided, and then entitled to vote at the said election. Every such nomination paper shall contain a declaration by the nominating Member that he has obtained the consent of the person whom he proposes as a candidate.

32. No exception shall be taken to any such nomination paper, or to the eligibility of any person so nominated otherwise than by a protest in the form in the Schedule provided, signed by ten Members of the College, duly registered as herein provided, and if any such protest shall within fifteen days after any such person has been declared to be elected be delivered to the Secretary of the College, he shall intimate the same forthwith to all the members of the Council inclusive of all persons (other than the persons objected to) who have been declared elected at the same election and shall convene a special meeting of the Council constituted as aforesaid, at which the signatories to the said protest shall be heard in such manner as the said special meeting may determine, and the person whose election is challenged, or the person nominating him, shall in like manner be heard in reply, and the said special meeting shall forthwith determine the matter in the said protest complained of, and shall either declare any person whose election is challenged to be duly elected, or shall declare his election to be void, and direct a supplementary election to the vacancy so created, to be held on a day not later than six weeks thereafter, and the rules and provisions for the purposes of any such supplementary election shall correspond as far as may be with the rules and provisions hereby enacted concerning the annual election.

33. On the eleventh day after the date of publication of notice of the said annual or other election, the Secretary shall cause the names of all the candidates nominated for election, together with the offices to which they have been nominated and the Members nominating them in each case, to be published in the Hall of the said College and the *Times* newspaper, and shall so soon as may be thereafter cause the same to be published in the *London Gazette*, and in two medical papers, and every such advertisement shall state which of the said candidates, if any, are proposed for re-election, and shall give notice of the place, day, and hour at which the meeting to proceed with the said election will be held, and shall state that any persons duly registered as herein provided is entitled to obtain from the Secretary a form of voting paper for the purposes of the said election, and that he may vote thereat in person, or by returning his voting paper signed by him, so that the same shall reach the College not later than the hour appointed for the commencement of the said meeting for election.

34. At the time appointed for the commencement of any such meeting for election, the Secretary shall produce publicly to the Presidents, or other person presiding at the said meeting, in the first place a copy of the Register of persons entitled to vote at the said election, and then the whole of the nomination papers which shall have been delivered to him in manner aforesaid, together with a copy of the advertisement thereof which he has caused to be published and the said advertisement shall be read from the chair; after which it shall be competent for any person who shall be duly registered as herein provided to apply to the Chairman for a ballot paper stating publicly his name and the date of his admission as a Member of the College, and if the said name appears upon the said Register delivered to the Chairman, he shall be entitled to have a ballot paper delivered to him forthwith; provided always that if any Member of the College shall make objections to him as a person not qualified to vote, he shall be called upon before receiving such ballot paper to sign a declaration in the form in the Schedule provided, and the ballot paper then delivered to him shall have the word "objection" stamped or printed upon the back thereof.

35. The ballot papers shall be forthwith marked by the persons to whom they have been delivered, and deposited by them in a ballot box, which shall be and remain in front of the Chairman for at least one hour from the commencement of the said election, and for so long thereafter as any persons claiming to be qualified shall present themselves, provided that the Chairman may at any time thereafter give notice publicly that he intends to close the election, and if during the fifteen minutes following upon such notice no person shall demand a ballot paper, the Chairman may leave the chair and declare the said election closed.

36. At some time during the continuance of said election, the Secretary shall produce to the Chairman the whole of the signed voting papers received by him down to the time of the comencement of the said election, and the whole of the requests for such voting papers received by him, enclosed in two sealed packets, and shall sign and deliver to Chairman a declaration in the form in the Schedule provided.

37. Upon leaving the chair, the Chairman shall name three persons, not being members of the Council, to be scrutineers, and they shall forthwith proceed, in the presence of any of the candidates or their nominators who may desire to be present, to count the votes given for each candidate by ballot, and shall open the said sealed packets and shall count the voting papers in like manner. Any voting paper may be objected to, and if so shall be marked with the word "objection," and when the said scrutineers have agreed upon the totals of the said votes the Chairman shall forthwith

declare the numbers publicly in the College Hall, and the persons having the highest number of votes shall be declared to be elected.

38. If the number of objections taken is sufficient in any case to invalidate, if they should be sustained, the election of any of the candidates so declared to be elected, the candidate having the next largest number of votes shall be entitled to enter a protest, which shall be forthwith decided on in the manner hereinbefore provided.

39. From and after the passing of this Act all vacancies occurring in the Court of Examiners shall be publicly notified in two medical papers, at least one calendar month before the date of the meeting at which the Council proceeds to elect examiners.

40. Any Member of the College, not being at that time a member of the Council, shall be eligible for election as Examiner, and any ten Fellows or Members of the College may propose the name of a fit person in writing to the Secretary within ten days after the date of such advertisement, and if any such nominations are received they shall be printed and circulated with the agenda of the meeting of the Council at which it is proposed to proceed to election.

41. Any fit person eligible as aforesaid, whether so nominated or not, may be proposed by any member of the Council present at the said meeting, and after all the nominations have been received, the Council shall proceed to elect by ballot.

42. In respect of all casual vacancies occurring in the Council between the date of one annual election and another, the Council may co-opt a Member of the College to hold office, but such Member shall in that case hold office until the day of such next annual election only.

43. *Interpretation Clause.*—In this Act the expression "Member of the College" shall include all Fellows of the College as well as Members of the College not being Fellows. The expression "medical papers" shall mean

. The expression "extraordinary expenditure" shall mean

44. This Act may be cited as the "Royal College of Surgeons Act, 1889."

Any suggestions upon the Bill should be sent to any of the members of the Committee appointed to carry the Bill through the Commons. The Committee consists of the following: Robert Collum, M.D.; W. A. Elliston, M.D.; Joseph Smith, Samuel Smith, George Danford Thomas, M.D.; Dr. Macdonald, Lawson Tait, F.R.C.S.; R. Davy, J. Tweedy, C. M. Jessop, Warwick G. Steele, M.D.; W. Ashton Ellis, J. Holmes, G. Pollock, Sir Guyer Hunter, Sir William Moore, Dr. Farquharson, R. Abud, M. G. Biggs, G. H. Cable, W. G. Dickinson, T. Stretch Dowse, Ralph Gooding, E. Hartley, Jabez Hogg, J. R. Kemp, J. W. B. Mason, C. Royston, W. Donald Smallpiece, John C. Smith, W. Wynn Westcott.

The Law Courts have been appealed to by the Fellows and Members who were threatened with expulsion, and it is significant and satisfactory to find that at once the College authorities hauled down their flag. Sturdy resistance as usual succeeded. This should encourage the rank and file of the profession to support their leaders. Those who have means should contribute; those who cannot afford a donation can give their moral support, and help the honorary secretaries in the hard work imposed on them.

Reviews.

Psycho-Therapeutics; or Treatment by Sleep and Suggestion. By C. Lloyd Tuckey, M.D. London: Ballière, Tindall, and Cox. 1889.

The enlightenment of public opinion under the influence of the scientific spirit, and the recognition of the fact that the phenomena of the visible universe take place in accordance with fixed and ascertainable laws, have conferred a benefit on humanity the extent of which it is hard for us fully to realise. The belief in ghosts and witchcraft entertained by profound thinkers like Sir Thomas Browne is inconceivable in the present day, except among the ignorant; and whatever startling phenomena we may meet with, we approach them fearlessly, fully confident that they can be explained and accounted for by the action of natural forces. Error, however, takes many forms: we often think we have dispelled it when we have only changed its aspect, and the habit of scientific thought may not have progressed without some evils following in its train. Constantly referring phenomena to their natural causes leads men to deny the reality of any phenomena, for which no adequate causes can be assigned, and where individual testimony is too strong to be resisted, a ready explanation is found in the capacity of the race for credulity and fraud. In the *brochure* now before us, Dr. Lloyd Tuckey essays to elucidate a series of doubtful phenomena of this class, and succeeds to a degree that will be variously estimated in proportion to the belief, or otherwise, in the facts, that the reader brings with him to its perusal. If, as is the more probable, he is unacquainted with the phenomena of hypnotism and suggestion, he will find in this little book much that will be new to him, much that will be startling by its strangeness; and before he will assent to the reality of these unfamiliar phenomena, he will demand evidence that they have been investigated with scientific accuracy; he will require them to be described with mathematical exactness. Readers of this class will hardly find the present volume convincing; the use of terms is too vague, the descriptions are wanting in precision. If, however, the reader is, from his experience or his studies, prepared to accept the facts of hypnotism, he will here find many an interesting account of its practice, and some ingenious illustrations of its theory.

The system of hypnotism described by Dr. Tuckey is the one which has been for many years employed by Dr. Liébault of Nancy, and has been elaborated by Professor Bernheim and others who are known as the Nancy school. The first chapter is designed to show the extent to which the mind, dominated by a powerful emotion, is capable of influencing the body, and many remarkable facts are brought together in illustration of this point, the most striking being the well-known case of Colonel Townsend, who was capable at will of inducing a state indistinguishable from actual death. In the second chapter it is shown that this susceptibility of the body to the influence of the mind is largely increased in certain conditions, notably in that form of deep sleep known as somnambulism; in which, under the influence of some over-mastering idea, actions may be performed involving the exercise of a degree of strength or skill of which the subject would be incapable in the waking state. In the third chapter we are shown how the Nancy School employ these facts therapeutically. The problem resolves itself into this: To induce a condition of sleep or somnambulism in the patient

and to supply him while in this state with ideas or dreams such as will tend to health. At Dr. Liébault's dispensary, these indications are carried out somewhat in this way. The patient is seated in a comfortable chair, is told to "think of nothing at all," and to fix his eyes on some special object. "Then the phenomena which attend the on-coming of sleep are gradually suggested to him: 'Your sight is growing dim and indistinct; your eyelids are becoming heavy; a numbness is creeping over your limbs; my voice seems muffled to you; you are getting more sleepy; you cannot keep your eyes open.'" The patient having been in this way sent to sleep, the operator proceeds to supply him with suitable ideas or dreams. "Let us suppose," says our author, "that the malady is chronic nervous headache"—a term, by the way, that does not appear in the nomenclature of diseases drawn up by the joint Committee of the College of Physicians. "The part of the head affected is gently rubbed, so that the patient's attention shall be attracted to it, and he is told that the pain is to disappear—that he will awake feeling his head cool, clear and comfortable, and that there is to be no return of the trouble." On awakening he probably feels quite well, and after a few sittings the symptoms do not return. This may be regarded as the fundamental experiment of the system: for the full details of its employment, and the class of cases to which it is applicable, we must refer the reader to Chapter iv. of Dr. Tuckey's book. In Chapter v. a number of cases successfully treated by hypnotism are quoted from the works of Professor Bernheim and others. Of his own experience of the treatment, the author says but little. His case of acute rheumatism, in which all symptoms disappeared in two days, is not recorded with sufficient detail to be of any value, and before it could be admitted as evidence, would need to be accompanied by an exact record of the medicinal and other treatment employed. We doubt whether in a disease which entails such serious consequences as acute rheumatism, and for which we possess so reliable a remedy as the salicylates, a practitioner would be justified in using hypnotism except in conjunction with the recognised treatment, and this of course renders conclusions as to the influence of the latter, drawn from isolated cases, of no value whatever. Our own limited experience of hypnotism leads us to the conclusion that its phenomena are real and cannot be explained on the supposition of fraud; but that its therapeutic influence, as is the case with so many new remedies, is apt to be overrated; —that, in fact, the operator himself is in danger of coming under the dominance of the idea that his results are more satisfactorily than they really are.

On the whole Dr. Tuckey's task has been well performed. The book sets forth the present state of the subject in a compendious and attractive form, and will largely help to bring treatment by suggestion under the notice of the profession in this country, who will then be enabled to find out and utilise whatever good may be in the system. T. R. Bradshaw, M.D.

On the Relief of Excessive and Dangerous Tympanites by Puncture of the Abdomen. A Memoir by John W. Ogle, M.A., M.D. Oxon. 8vo, pp. 111. London, 1888.

Probably many of our readers may be unaware of the frequent occurrence, in medical literature, of mention of the above-named remedial measure. Dr. Ogle, in the "memoir" before us, has gathered from the records of observers, ancient and modern, and from recent systematic works, notices extending to close upon sixty pages of the literature of the subject. The author, in the year 1871, saw two cases "in which death was apparently the direct result of unrelieved excessive tympanites (no other serious affection being discovered after death; instances as it were of *mors sine morbo*) which determined him not to lose any opportunity of suggesting relief in such momentous cases, after all other means had been tried, by the simple and readily-performed operation of puncturing the abdomen" (p. 6). A successful case determined Dr. Ogle to ascertain "what views had been transmitted by predecessors, and what had been recommended or achieved by contemporaries in connection with the matter." The result of the enquiry is embodied in citations collated from various sources, and contained in the first sixty pages of the work in hand, which is an extension of remarks that had appeared in the *Lancet*, July, 1887. The *modus operandi* adopted by various physicians and surgeons is described. The use of simple trochar and cannula is that which has been most frequently adopted, and appears to have been as efficient as aspiration. The position assumed by the author derives support by illustrations from the writings of practitioners in veterinary medicine and others, of which numerous instances are cited. "Such," Dr. Ogle observes, "are the references to standard authorities and the illustrative cases supplied to me by living practical physicians and surgeons, 'the joint force and full result' of which will, I think, suffice indisputably to indicate the great good which may be accomplished by the expedient, when timely adopted, of puncturing the abdomen with a fine trochar. . . . . Consideration of the references given will show that the weight of evidence, the preponderance of testimony, is in favour of, and warrants this operative measure. . . . . That it is incontestably, when resorted to with circumspection and deliberation, a legitimate procedure, attended by most benign results, one that may be undertaken *tuto, celeriter, et jucunde;* at any rate, that it has strong evidence in its favour as a *dernier ressort*" (p. 85). We would conclude by the expression of the conviction that this memoir constitutes a valuable contribution to practical medicine, as well as a sterling addition to the literature of the medical sciences, to be consulted by all who may require information upon the subject of treatment in excessive and dangerous tympanites. W. B. Kesteven, M.D.

On Syphilitic Affections of the Nervous System; their Diagnosis and Treatment. By T. McCall Anderson, M.D., Professor of Clinical Medicine in the University of Glasgow. 8vo, pp. 89. Glasgow, 1889.

"Is mercury an antidote to syphilis?" is the question that Dr. McCall Anderson has here undertaken to answer. "My view," he observes, "may be thus stated: that just because 'mild' syphilis is apt to be treated in a cavalier fashion, and without due care and persistence, disease of the nervous system is very apt to follow in its wake; and that such disease is much more common than is generally supposed." Dr. Anderson bases this statement upon twenty-four cases which have occurred recently in his practice, of which he has sufficiently accurate records, though they constitute but a fraction of those which have come under his observation. The perusal of these cases, as recorded by Dr. Anderson, will satisfy any reader that they constitute "sufficiently accurate records." The impression made by the perusal is that here we have a master hand at case-taking—a "clinical Professor," who possesses the faculty of seizing all essential

points in every case upon which he bestows his attention. With such qualifications Dr. McCall Anderson must be no slight acquisition to the University of Glasgow.

Having gone through the clinical history of the twenty-four cases of syphilitic disease of the nervous system, to which reference has been made, the author enters upon the consideration of diagnosis and treatment. Under the former the following are the principal points treated of:—1. *The History of the Entrance of the Syphilitic Poison into the System.*—2. *The Discovery of other Manifestations of Syphilis.*—3. *The Discovery of Traces of Bygone Syphilitic Manifestations.*—4. *The Presence, or the History of Pain in the Joints, Bones, or Head.*—5. *The Appearance of the Patient.*—6. *The Age and Sex of the Patient.*—7. *Occupation of the Patient.*—8. *Syphilitic Nervous Lesions are frequently Multiple.*—9. *Variability of Symptoms.*—10. *Certain Fundamental Types in Cerebral Syphilis.*—11. *Eye Symptoms.*—12. *Syphilitic Affections of Other Viscera.*—13. *Results of Treatment.* The subject of treatment is comprised by the author in a few terse paragraphs, the gist of which is that mercury cannot be dispensed with in the treatment of syphilis. "Whenever," says Dr. McCall Anderson, "we suspect that a nervous affection is of a syphilitic nature we should attack it at once with antisyphilitic remedies, and just as energetically as if we were absolutely certain of our diagnosis. A faltering hand under such circumstances is fatal. A very prevalent belief with regard to the treatment of syphilis is that mercury is *the* remedy in the early, and the iodides in the late stages. Now I admit that iodine is *most* useful in the latter, and that mercury is *very* useful in the former; but at the same time I hold that some of the most brilliant results are achieved by mercury in old-standing cases of syphilis, and sometimes after iodide of potassium has failed." The modes in which the remedy has been employed by Dr. Anderson may be culled from the details of the cases that are given in this work. An appendix gives the discussion that took place in the Medical Section of the British Medical Association upon the treatment of syphilitic affections of the nervous system, at Glasgow, in August, 1888.

A Defence of Electrolysis in Urethral Strictures, with Documentary Evidence. By Robert Newman, M.D., New York. PP. 20. Philadelphia, 1888.

The object of this pamphlet is to review some alleged recent failures in the treatment of urethral stricture according to the electric method. Dr. Newman has, he states, applied his method of electrolysis successfully to the treatment of urethral structures for the last nineteen years. Further, Dr. Newman gives the names of many other practitioners who have followed his method. "With such evidence from at home and abroad," the author adds, "it is no longer a question as to the recognition or success of the method. The only point is, what is necessary to constitute a successful operator. For that, it is an absolute necessity to be an electrician and a genito-urinary surgeon." For want of the possession of the combination of these attributes failures have occurred, and have been recorded as objections, fatal to the adoption of the electrolytic treatment. These "failures" and objections Dr. Newman examines, and successfully refutes. One source of failure we may note in the title of a paper on "Electrolysis in Spasmodic Stricture." A spasmodic stricture, as Dr. Newman remarks, "is an ill-advised expression, since mere spasmodic action is *never a* stricture; and electrolysis will not cure or benefit a spasm, but, on the contrary, may cause a spasmodic action, thereby making passage of the instrument impossible." Dr. Newman speaks only of the success of electrolysis in organic stricture. The employment of the galvano-caustic current is obviously inapplicable, and calculated to do harm instead of conferring a benefit. Our readers will find a full and clear exposition of this subject by Dr. Steavenson in the last July number of this journal, from which paper we quote the following observations. "The present method is electrolysis, with weak currents applied at long intervals, resulting in galvano-chemical absorption, known and recognised as Newman's method. Newman not only introduced and perfected the electrolytic method, but also invented and perfected instruments for use in the operations, so that failure in the operation is hardly possible. In England, eminent surgeons so fully comprehend and acknowledge the great value of this method, that it is taught at the medical schools as one of the ways of treatment of urethral strictures." Dr. Newman subjoins several letters from members of the profession who have successfully adopted his method. Had this mode of treatment been known some years back, we would suggest the profession might have been spared the heart-burnings and recriminations, as to the "Perineal Section," that took place between two of the most distinguished ornaments of Scottish surgical science. The judicious employment of electrolysis in the future will prove a boon to sufferers, at the same time preventive, of incurable disease and lingering torment.

W. B. Kesteven, M.D.

The Construction and Maintenance of School Infirmaries and Sanatoria.

This is an excellent little work, prepared by the Council and Medical Officers of the Schools' Association, and should be in the hands of every schoolmaster and every medical officer to a school. It is concise and well arranged, is illustrated by plans, and has a very full index, so that reference to any particular point is much facilitated. The first section deals with the infirmary—its site, construction, foundation, building materials, floors, etc. The general arrangements of the interior, warming and ventilation, water supply, sewerage, and gas pipes, are all questions which have been ably considered; rules are laid down for administration, which, if strictly adhered to, should leave little to be desired. The second section relates to the sanatorium, or building intended for infectious diseases only; this is also treated of in a most satisfactory manner on somewhat similar lines to the first section. Nothing of importance seems to have been omitted, and a surprising amount of valuable information has been condensed into a very small compass.

H. R. H.

Elements of Pharmacy, Materia Medica, and Therapeutics. By William Whitta, M.D., etc. With Lithographs and Woodcuts. Fifth edition. London: H. Renshaw. 1889.

We welcome a fifth edition of this excellent text book. It is admirably arranged and possesses this advantage, that it is useful to the student and practitioner. It tells how pills, mixtures, etc., are to be made and dispensed, how prescriptions are to be written and read. It gives an account of materia medica, whilst the chapters on therapeutics are admirable for their conciseness and soundness. The non-official remedies, which are swelling daily in number, are treated in a separate division, so that the book really ranges over the whole subject. The general practitioner who desires to keep pace with therapeutic advance will find this work an admirable guide both to the old and new remedies.

The Provincial Medical Journal,

APRIL, 1889.

WE published in the last issue of the PROVINCIAL MEDICAL JOURNAL a very important manifesto, evidently directed against the management of the *British Medical Journal*. The action of the editor in publishing a script of the late EMPEROR of Germany was made the peg on which to hang a number of complaints, and the issue of this requisition may be regarded as the outcome of the first agitation. The *British Medical Journal*, by its business management and close attention to its advertisers, has been made an excellent property, its income from advertisements alone being almost equal to what is received from its subscribers. We should not be far wrong in saying that its circulation was three times as great as the *Lancet's*, so that advertisers reap all the advantages which must follow from so large a circulation. But advertisers are not content with simple announcements, for which they have paid: they expect, in addition, some paragraphs pointing out the excellencies or peculiar features of their wares. They are strictly within their rights in asking for notices, if the articles submitted for examination be good, and really worthy of notice. The *British Medical Journal* has always been ready to give notices, and hence it has built up an excellent *clientele* of advertisers. This is clearly, from a business point of view, in every way satisfactory; and if the *British Medical Journal* were a limited liability company, and the shareholders entitled to dividends, and the money now distributed for scientific purposes were devoted to payment of dividends, a vote of thanks would be given to the editor and managers of the paper for their cleverness and ability in securing such substantial proceeds. But the British Medical Association, though a limited liability company, does not exist for the purposes of trade; its journal is not a mere money-making concern beyond a certain point: it cannot exist without financial support. It is within the members' rights to consider whether they prefer to have a purely scientific journal with a small income, or a semi-scientific journal with a large income. The advertisement sheets can be readily cut down by the exclusion from its columns of such articles as vinolia, and other patent medicines, and by the withholding of laudatory paragraphs of all kinds in the body of the journal, and consequently, the receipts will be very materially diminished. There would still remain a permanent income of £15,000 a year from subscribers, and a good income from what may be called pure pharmaceutical advertisements, but the available income would consequently be less. The branches will have fully to consider what diminution of income means before they pledge themselves to support the memorialists.

Exception has been taken to the method adopted by the editor, as regards the non-signing of reviews and leading articles. We are thoroughly in agreement with the petitioners in the matter of reviews. The *Lancet* and *British Medical Journal* reviews are utterly valueless from a literary point of view. The routine style in which the books are usually handled evidently indicate that the reviewing is a mere matter of form. If the reviews were signed, the work would be better done, and there would be some guarantee that the reviewer himself knew something of the subject he undertook to analyse. If we look at the custom adopted by such a journal as *Nature*, we shall see the advantage of the signed review. In that journal the signature to a review is an indication that the work has received the careful consideration of an expert in the same department of which the work treats; and, as a rule, it is more gratifying to an author to have the opinion of a trained mind on his work. Of course, there are a few writers who prefer laudatory reviews, by whoever written. The anonymous review opens out a field for incompetence, slovenliness, and for personal animosity. Reviewers of repute who are willing to append their names, can readily be found, if they be offered adequate remuneration. The *British Medical Journal* is in a position to pay for this kind of work better than it does. This change is one which we hope will be adopted.

As regards the signing of leading articles, we cannot agree with the requisitionists. The journal must have a policy, definite views, and the editorial direction must be clearly indicated through the leading articles. He has the right to modify and alter all the articles submitted to him, and he is alone responsible for what appears in the columns included under the *we*. There can be only one editor, just as there can be only one captain of a ship. If the editorial policy be wrong, then, of course, the management committee should step in, and try to induce him to alter it; but so long as the editor has the confidence of the committee, there is hardly any ground for complaint.

It is no easy matter to feel the pulse of 13,000 or 15,000 members, and accurately record its beat; and the man at the wheel of the *British Medical Journal* must be in a measure independent, and able to steer a clear course, uninfluenced by side winds, doing what is best for the general welfare of the profession, apart from all cliques and parties, and fearless of criticism. This independence may be combined with a conciliatory disposition, and due regard for the opinions of members. A weak man would very soon wreck a journal. Criticism on the work of the British Medical Association is not to be deprecated. We have been pretty outspoken, when occasion required it, on the action of the Council and on the journal; and as regards the present state of affairs, we believe that the Council need not feel any surprise at the action of the requisitionists. It is not very extraordinary that the opinion of the branches should be asked as to the points in dispute. The branches are independent, and quite capable of forming an opinion on any subject submitted to them, and any attempt made to control the branches would be most deleterious to the best interests of the Association.

The influence of Carlsbad water in the prevention and cure of disease has long been practically tested, and various theories as to the *modus operandi* of the waters have been from time to time put forward. Patients who visit Carlsbad are undoubtedly benefited, and those who cannot do so, but drink the waters imported, are also much benefited. Many papers have been written on the use and influence of the Carlsbad waters, and among the more recent and useful is one by Dr. Dumas Leclercq, read at the New York of Medicine, "On the Influence of Carlsbad Water on Uric Acid and Excretion." In this paper Dr. Leclercq detailed the results of a number of experiments on himself and others, and he offers a reasonable explanation of the well-known beneficial effects of the Carlsbad waters on gouty patients. In these patients there is amelioration of the worst symptoms: albuminuria, inflammations of the renal pelvis, nervous troubles, as hypochondria, melancholia, hysteria, disappear. According to Dr. Leclercq these complications are produced by excessive quantities of uric acid dissolved in the blood, and hence by the imbibing of the warm alkaline water which becomes rapidly diffused in the blood, a prompt discharge takes place, the diluted urine which soon becomes alkaline, in a short time removes the surplus acid circulating in the blood. Gouty attacks, formerly frequent, are kept off for some time, or become less intense after a course of the mineral waters. With regard to this therapeutical effect, Dr. Leclercq is not satisfied with the explanation of a washing-out process, but inclines to the view that the diathesis is mitigated. In support of this view the author refers to the researches of Charcot Minkowski, Kossel, Chryonsyecyewski, and Pawlinoff. According to Minkowski the liver has a third function besides that of gall secretion and glycogen formation—viz., the synthetic formation of uric acid. The sulphate of soda, so plentiful in Carlsbad mineral waters, considerably stimulates gall secretion, and also probably influences uric acid formation. From this standpoint, we can understand the direct topical action of Carlsbad on the liver, and explain its recognised beneficial influence at least in many phases and forms of gout. Still more, according to Garrod, these mineral waters are indicated in gout, for the reason that the diathesis leading to its production interferes with hepatic functions; whilst Ebstien recommends them particularly in those forms of gout complicated with plethora or gastric symptoms. We give Dr. Leclercq's conclusions in his own words:

"The compound action of Carlsbad water arises in the first place from the influence of the warm water itself, which, 'when absorbed in large quantities, powerfully stimulates the process of the animal economy and increases the various secretions' (Garrod) and secondly from the salts. With regard to these, the facts placed beyond doubt by experiments are the following: Sulphate of soda produces increased peristalsis and excretion of water, urine, and urea. The cathartic action cuts short, so to speak, complete digestion and absorption of the ingesta. Excretory matters, which would otherwise be retained (and possibly cause auto-infection?), are quicker eliminated than sub norma. Chloride of sodium greatly excites the stomach's functions and induces increase of urine and of the nitrogenous excretion; while carbonate of soda improves the digestive power of the stomach, increases peristalsis, and exalts the natural alkalinity of the blood. If now by virtue of the properties of the constituents of the Carlsbad water, there is an increase of peristalsis and diuresis, and an increased flow of liquids in the tissue, while plenty of out-door exercise and baths are taken, and less food—which is partly cut short, partly eagerly assimilated, owing to a hunger of the protoplasm—fewer products of the regressive metamorphosis will circulate in the blood and organs, while those that circulate are more easily eliminated on account of the diuretic effect and the increase of all secretory functions. Finally, the secretions are not only increased by the Carlsbad water, but also the pressure under which they are secreted is raised by sipping fluids. This is most likely due to nervous influence, for Kronecker shows that a liquid taken in many small sips will for the time completely abolish the inhibitory action of the vagus of the heart. Brunton calls attention to this fact "in consequence of which Carlsbad water, when taken in numerous sips for an hour or more, as at Carlsbad itself, is so exceedingly efficacious in hepatic diseases." This consideration will serve to assist us in explaining how certain predispositions of tissues, like the cartilage, to receive injuries in gout may be effectually combated with the Carlsbad mineral water. The increased pressure just referred to, would be beneficial by increasing the 'vis a tergo' in such organs as have a torpid tissue change, owing to the total absence of blood-vessels or their scant distribution at long intervals between the capillary vessels. The alimentary liquid being now easier renewed the conditions are not favourable for a deposit of urates."

"We must not look a gift-horse in the mouth," is a very old saying, so that, applying this principle, it might appear wise not too closely to criticise or examine the foundation upon which rests the new gift towards the treatment of locomotor ataxy, given by the illustrious Charcot. For the present we must only chronicle some of the facts relating to this new departure, reserving for subsequent consideration the theory upon which suspension is based, for this is an age of theories, though they often run wild. The pathological anatomy of sclerosis in its various manifestations would hardly *primâ facie* incline us to favour suspension as a mode of cure. But we must not on the present occasion run into pathology, but confine ourselves to those many-sided things called facts.

Locomotor ataxy, though we have known cases which have ended in what we might almost call recovery, is not a hopeful disease to treat, more especially when it depends, or is associated with, syphilis, so that any hope of relief of

some of the distressing symptoms, as the lancinating pains, or weak equilibration, and bladder trouble, must be welcomed. When M. Charcot, then, tells us that by means of suspension he has relieved and improved the condition of these ataxic patients, our readers would naturally like to hear how this is effected. Most surgeons are familiar with the suspension apparatus introduced by Lewis Sayre, of New York, and M. Charcot avails himself of a modified apparatus of Sayre. The ataxic patient is placed in the apparatus, which is properly adjusted under the neck, chin, and shoulders, and then traction is applied gently, and the patient is lifted off the ground. The vertebral column is thus acted upon and elongated, whilst the structures of the neck are very severely tested by the strain put upon them. The period of suspension rarely exceeds two minutes, and is carried out on alternate days. The patient is let down in as gentle a manner as possible. Weight plays a very important part in the time the patient is suspended. The personal attention of the physician is required at each operation, whilst a skilled assistant is also absolutely necessary. It is to be hoped that suspension will not become as fashionable as massage, and that we shall not have a mushroom class of rivals of Berry, who would go in for scientific hanging as a profession, for if so we fear that the results will not be in all cases satisfactory. The results obtained by Charcot were published in the *Progrès Médical* of February 23rd, 1889, and they have already attracted the attention of the profession in Germany and England, and Drs. Eulenbrug, Mendel (Berlin), De Watteville (London), Saundby (Birmingham), have adopted the system. The Berlin physicians confirm the encouraging report of Charcot after using the method on twenty ataxics, and De Watteville and Saundby appear to consider the method worthy of trial. De Watteville has made a modification on the suspension apparatus of Sayre, as he does not favour the tripod, though Dr. Saundby is of opinion that the tripod is quite suitable for the purpose. De Watteville has translated Professor Charcot's memoir. We think that the following paragraph is a wise one. "The most sanguine observer must acknowledge that it is entirely premature to come to any definite conclusions upon a point of such deep perplexity as the question of the possibility of absolute cure in locomotor ataxy. Physician and patient alike must beware from falling into the temptation of conceiving exaggerated hopes as to the final results, in the presence even of effects as incontrovertible as those testified by so many critical observers."

In a conversation with a very intelligent practitioner, he raised the following defence for shilling dispensaries: "The whole evil," he said, "arises from the fact that a certain number of medical men are willing to give their services gratuitously. They carry on two kinds of practice—receiving fees at their residences, and prescribing for nothing, not for the poor, but for all classes, at their hospital consulting rooms. One system helping the other, the hospital appointment being really a stepping-stone to success. The hospitals are ruining the profession; for the authorities of institutions getting, what is the prime factor, medical advice for nothing, are utterly regardless of the general welfare of the profession at large; and, trading as they do, are careless as to whether the recipients of this free medical relief are deserving of it or not. If they had to pay for each medical prescription written, even a very small sum, they would not be so ready to scatter broadcast these medical orders. This evil is the parent of all the other evils from which the profession is suffering. It is difficult to suggest a remedy, but there is only one—viz., to make it penal to give free medical advice. As regards the poor there will be no hardship, as the State should, and does interfere. The country is now well supplied with Poor-law medical officers, and England is filled with admirably constructed union infirmaries, besides its dispensaries, for paupers—a name that should be unknown in England—though the pauper is seen at the voluntary hospital in luxuriance, accepting eleemosynary air without a blush. Humanitarianism and so-called philanthropy are largely responsible for the present position of affairs, whilst the teachers and lecturers, who tell students that 'they should be consoled for failure by the consciousness of the nature of their work,' have also a good deal to answer for. From successful men, who have raked in their pile, this advice savours too much of humbug to be swallowed except by Verdant Greens. What can young men do? They see the old and experienced at hospitals greedily appropriating the patients who might fall into their hands. They cannot compete on equal terms, or obtain adequate fees, so they meet the difficulty in this extraordinary competition by opening shilling dispensaries, to which people flock, in large numbers, and they make a living, where otherwise they would be compelled to starve.

"It is a matter of common sense. Young men are intelligent, and can now see that all this high talk about the nobility of the profession is arrant nonsense. Men must live and pay their way. They cannot exist under any other conditions but those which regulate all other professions; and finding the means in the shilling dispensaries, they adopt this system. How will it end? It will end by the establishment of all kinds of these institutions—some for eye diseases and surgery, some for orthopœdics and skin diseases; and in turn, the profession will be brought to such a pitch that the evil will cure itself, but by the very severe process of extinguishing the whole hospital system, which for over a hundred years has been like an incubus on the profession. Why should the younger men care for what is said about them? Have the seniors who hold hospital appointments ever considered their interests?

"The few men, who in all our towns hold the hospital appointments, have hitherto shown themselves utterly regardless of the general welfare of the profession. Now it is the turn of the younger men, and as long as men can

make a good living out of shilling dispensaries, they will laugh at all condemnation, and continue their course of action. Their is nothing to prevent them from charging any fee they choose to accept. The British Medical Association cannot interfere. It started provident dispensaries through its journal, and Mr. Ernest Hart was one of the chief agents in their spreading through the country. What is the difference between a private and public provident dispensary? Not much; one, it is true, is a recognised system, but the profession can, if it likes, adopt both systems. I grant that the profession is deteriorating, and I think that medicine is nearly played out as a profession, and I would not allow a son of mine to take it up as a means of living; but if he did I should instruct him to carry it on on business lines, and he would then make it remunerative.

"You want reform, but you must be fair, and not press on those who are compelled *through evils, not of their own creating*, to take up this line of practice. You have my views, as you have asked for them. One other point. Ask the commercial travellers who go round about their customers. They will tell you that they receive the largest orders from the owners of private dispensaries, whose waiting-rooms are crowded, and they also are good payers. In large towns, like Liverpool, the provident dispensary is a most lucrative system of practice. You don't agree with the system? Well, suggest a remedy. You will find that you will have a difficult task, unless you begin at the root of the evil—the hospitals."

The profession will have to take into account such views as those above published. We are evidently in a very bad transitional state if such views are generally acceptable. But this is not the worst. The hospitals are blamed as being the cause of our troubles, and truly if we may believe the editor of the journal called *The Hospital*, we are threatened with another danger. We are to be supplanted in due time by the hospital nurse and the educated chemist. We are *not* to be effaced, but to be "compulsorily elevated." Here is a sample of how this is to take place, and why: "By a process of natural selection the profession is everywhere dividing itself by sharp lines of cleavage into two classes. There is the cheap class of dispensers who take shops, advertise like any other tradesman, and who to all intents and purposes belong to the lower ranks of chemists and druggists. On the other hand is the more numerous class of educated men, who, while not suffering themselves to be bound by the chains of a merely formal and meaningless etiquette, stand firmly by the best traditions of the past, and bind themselves together into a great army for the advancement of their science, the improvement of their art, and the maintenance of a noble enthusiasm, and a fervent *esprit de corps*." The last few words are conceived in the good old style, so dear to the authors of introductory lectures. The noble profession is evidently between two millstones—but to continue our quotation:—

"The process of adapting themselves to their new conditions cannot be carried out by the doctors without a good deal of privation and suffering. For just as the introduction of machinery made the demand for human labour smaller, so is the rise of the chemist and of the trained nurse diminishing the necessity for the frequent calls and the close personal supervision of the medical attendant. In acute and dangerous cases the morning, and in some instances the evening and mid-day call will be needed as before. But in lingering and chronic illnesses, where the trained nurse is always on the spot to watch and to report, and to send a swift messenger in the event of need, the daily visit will give place to the bi-weekly, or even to the less frequent call. Of course when visits are fewer in number fees will necessarily rise; but they can never rise so high as to compensate for the more frequent calls of former days. The doctor's income, already far too small, must become still smaller, and his struggle for survival still more severe. In due time, however, the reward will come, and the public as well as the medical profession will share in its advantages. As frequent calls upon patients become less indispensable, and fees rise, the doctor will be able to live without such a tremendous strain and expenditure of energy as he is now compelled to endure. He will have both leisure and strength to do that without which the ablest man in the world cannot keep pace with the best progress of the times. He will be able to read and to study, and, what is as necessary as either, to meet his professional brethren in frequent and friendly conference and discussion.

"The public at large have a much more immediate and practical interest in this question than they suppose. The medical profession has always offered a career to a certain proportion of the clever youth of the country. With the rise of the trained nurse and the educated chemist the field for doctors is necessarily very much limited in area, and the prospects of success, or even of a livelihood, are correspondingly diminished. There seems to be as yet no general comprehension of this fact; because young men are flocking to the gates of the profession in increasing numbers year by year. Of course, a medical education can by no possibility do those young men any harm—on the contrary, it may be of very great service to them. But it is certain that many of them will never make use of it as a means of earning a livelihood, because it will not be worth their while to do so. To all those, therefore, whose means are limited, and whose resources will not enable them to qualify for a second profession if the first they choose should fail them, the advice is given with much seriousness—to think well before they adventure themselves upon a medical career. The number of candidates for medical openings is, owing to the causes we have indicated, still more rapidly diminishing. When men increase in excess of the demand for their services there is but one result possible—starvation for many, and keen competition for all."

The concluding words are plain enough. Hospitalism, if it has to land the profession into such a state as above described, should be at once supressed in the interests, not of the profession, but of society at large.

Annotations.

"Forsan et hæc olim meminisse juvabit."

GENERAL MEDICAL COUNCIL MINUTES.

Volume 24 of the Council's Minutes for the year 1888 is now ready, and includes four appendices, one consisting of the Fourth Report by the Statistical Committee, containing a census (with diagrams) of the registered medical practitioners in England and Wales for the years 1881 and 1886; another consisting of Documents relating to a Memorandum by the president on the Disciplinary or Penal Powers of the Qualifying Medical Authorities and of the General Council (a subject which is further considered and developed with a suggested amending Bill, on pp. 11-24 of the confirmed minutes of the Executive Committee of Feb. 25th, 1889); and a third appendix giving the Inspectors' Reports and General Commentaries on the different Final Examinations; together with remarks thereon by the Bodies inspected.

THE MEDICAL REGISTER.

The "Medical and Dentists' Registers" and the "Students' Register" for the current year, were published on Saturday, the 9th March. The "Medical Register" has been subjected to the most thorough revision, and has been made complete according to the latest possible information. In addition to all the Medical Acts from the year 1858 down to the most recent Act of 1866, it will be found to contain much statistical information, including a table showing the total number of practitioners registered from 1858 down to the present time, and the number now remaining on the Register—viz., 27,936; and a table showing the qualifications granted by separate or conjoint examining Bodies, which entitle the holder to primary registration; and further, a table giving a list of the several foreign degrees in medicine which are now registrable, as additional titles, by practitioners previously registered. The "Dentists' Register" has been carefully corrected also to the latest possible date, and contains information as to the number of practitioners whose names now appear in it, either as Licentiates of the various Licensing Bodies, or as having been engaged in practice before the passing of the Act: the percentage of Licentiates being increased to 20.83 of the whole number, and that of those registered only "as in practice before July 22, 1878" being reduced to 78.46. The List of Dental Students, formerly published at the end of this Register, has been removed, on the representation of the British Medical Association, for while the object of its publication was to afford useful information in regard to those studying for the profession until these names could be taken out of the list of students and inserted in that of practitioners, it was found to be used by some to convey the misapprehension that they were already registered practitioners. The "Medical Students' Register" as usual gives, in addition to the list of those registered during 1888, statistical tables showing the relative numbers in which students passed the several recognised preliminary examinations entitling to registration, and the various places of medical study where they commenced their professional course.

THE INTERCOLONIAL MEDICAL CONGRESS.

It is gratifying to us to be able to congratulate the profession of Australia on the success of the second International Medical Congress, which commenced its sittings at Melbourne on January 7th. The proceedings were opened by His Excellency Sir Henry Lock, K.C.B., Governor of Victoria. visitors were received by the Hon. W. D. Gillies, Premier of Victoria. The Congress was fortunate in having as president the well-known surgeon, J. H. Fitzgerald, who is not only the most illustrious surgeon in Australia, but who has a world-wide fame; and his address was well worthy of the occasion, and well deserved the reception accorded to it. The proceedings came to a close on January 12th. The next sitting of the Congress will take place at Sydney in 1892, under the presidency of Dr. H. N. MacLaurin. The Congress was divided into the usual sections, and there was an ample supply of material and of members.

ADVERTISING IN LAY PAPERS.

The British Gynæcological Society is to be congratulated on the resolution passed at the meeting on March 13th, condemning the advertisement of medical works in lay papers. The resolution, proposed by Mr. Lawson Tait and seconded by Dr. Granville Bantock, was general, without any personal bias, and without mentioning any names. The medical journals afford ample opportunity for authors to make their works known to the profession; and to appeal to the lay public, especially with works that deal with diseases of women, savours of quackery of the worst kind. Many shafts have been aimed at gynæcologists, and much discredit has been brought upon them by a few black sheep, so that the efforts of the British Gynæcological Society to keep its fellows pure will be appreciated by the profession.

HYDROPHOBIA IN GERMANY.

During the year 1888, only four deaths from hydrophobia were recorded in Germany. This result is significant, more especially as Germany did not send any patients to Pasteur, and is without a Pasteur Institute. When we look at the extent of country and its close proximity to the French frontier, this low mortality is all the more remarkable, and more especially in view of the thousands of French people who are reported to have been bitten by rabid dogs. The French have much to learn, and they should send a commission to Germany to enquire how the Germans manage to have such a low death-rate. To us the explanation is simple. So far back as 1881 we explained how hydrophobia may be prevented.

MAMMONITE THRIFT.

Punch has contributed the following admirable diatribe against infant slaughter, a subject we have often written about.

(The Right Hon. W. H. Smith on his way to the House of Commons with the Estimates under his arm) :—

Mr. Punch—"Estimates! Yes, but there's something further for you to look after, Mr. Smith—the surplus population!"

"When a Mammonite mother kills her babe for a burial-fee,
And Timour-Mammon grins on a pile of children's bones."
Tennyson's "Maud."

"The strongest statement in favour of infant insurance is that it encourages thrift.—*Mr. Braxton Hicks on Infantile Insurance.*"

"It is clear, he remarks, that to allow a poor parent to effect an insurance on his child's life gives him a direct interest in its death."—*The "Times" on Mr. Braxton Hicks' Letter.*

"Thrift, thrift!" O convenient Death!
Wise counsel he whispereth under his breath
Into pitiful poverty's ear!
Poverty makes even parentage keen
At catching his sinister hints. 'Tis a scene
For a new *Danse Macabre;* that bald bony nowl
Crape-canopied craftily set cheek-by-jowl
With the conscienceless vassal of Beer.

"Thrift, thrift!" It is surely the last subtle shift
Of the Spectre to pose as a preacher of Thrift!

True, Mammon and Mors have been ever allies;
But here is a scene that might almost surprise
The Moloch for whom they both cater.
The cynical grin of the fiend of the flame
Might melt me to a look of compassionate shame
At sight of the Golden God's last little game,
Which should bring a hot blush to a satyr.

QUACK MEDICINES AND RELIGIOUS PAPERS.

Religious journals in England appear to make a speciality of securing quack advertisements, and we learn from one of our exchanges that in the United States the same class of journal cultivates the patronage of the quack. Dr. T. C. Minor puts the matter very clearly. "Without such 'ads.' theological journals would not thrive in the United States; and this tendency to perpetuate fraud through unscrupulous journalism has now extended like a pestilence to the lay journals of the land. The mischief wrought by these foul destroyers of soul, mind, and body is incalculable; they are corrupters of morality, the insidious iconoclasts of public virtue and the paid agents of vice; the price of the 'ad.' soothes each drowsy conscience in a land where the struggle is for wealth, no matter how close the victim grazes the penitentiary bars in the pursuit of gain. The religious journals of the country have for years been the panderers to the vendors of abortive remedies; Christ is crucified in one column and pennyroyal and cotton-wood pills praised on the opposite page. It is no wonder that physicians, year by year, are evidencing a wider tendency to denounce religious and so-called moral journalism. The most sensational morning journal in the country would modestly shrink from publishing the filthy 'ads.' found in some of the religious weeklies of the United States, where the 'retired clergyman, ruined by early indiscretion,' etc., publishes his cards with the holy address of 'Bible House,' New York. It seems to be a popular belief that the regular medical profession objects to patent medicine because it interferes with their practice; such is not the case, for these nostrums are largely responsible for the Bright's disease and bladder troubles of this country. Every dozen bottles of patent medicine sold over the druggist's counter makes a patient for the doctor. It is not difficult to cure disease sometimes, but the present epidemic of patent medicine damphoolery, nurtured and fostered in the interests of the various churches of America, should be restrained. If clergymen desire respect for their calling, they should preach what they practice. The 'Bitters' in the study closet, while an aid to preparing the usual dull Sunday sermon, have enough alcohol in them to induce the clerical cirrhosis of the liver, or theological brain softening, which seems to be a common complaint just at the present period."

HIGH *VERSUS* LOW DRESSES.

The low dresses so much in fashion have been the cause of much illness, frequently followed by death; but the tyrant fashion has required her victims, and under her car of Juggernaut women have prostrated themselves, and have thus been virtually sacrificed. It is useless for medical men to cry out against fashion, though it is our duty to do so. We have forbidden in India the sacrifice of women to their husbands' manes. This seemed to us a horrible sacrifice. Sacrifices to fashion in this country are so common that we do not mind them. The intelligent Chinaman who has been investigating our habits, might well wonder at some of our fashionable customs, and might truly tell us that reform is wanted very much indeed in the toilets of our women.

SUPERANNUATION OF POOR-LAW MEDICAL OFFICERS.

After fifty years' service under the Thetford Board of Guardians, Mr. Archer, Medical Officer, was refused superannuation. To the credit of the Board the resolution was subsequently rescinded, and we believe he has since obtained it. Superannuation is accepted in principle by the Local Government Board; but unfortunately the little word "may" stands in the Act, and the Guardians too frequently indulge their economical tendencies by interpreting the Act in the way they like. We are able, however, to point to many Boards which have interpreted the Act in a liberal manner, by granting superannuation to deserving officers. It is not always possible for a medical officer to make provision against old age or sickness. However provident he may be, exigencies arise which destroy all possible foresight. "Shall" for "may" is all we want.

THE ABUSE OF MASSAGE.

AT the meeting of British Gynæcological Society on March 13th, Dr. Macnaughton Jones made an able and trenchant attack upon the abuse of massage. Like all fashionable modes of treatment, it has been taken up by *entrepreneurs*, who saw in it a chance of making money out of the credulous; and we regret to say that within the professional fold there have been found a few who have laid themselves open to suspicion. The advantages of massage are indisputable, its abuse is also indisputable. Its extension to the gynæcological department of medicine has led to the most deplorable abuses. The "speculum" practitioners are nowhere compared with the professors of vaginal and abdominal massage. The timely warning given by Dr. Macnaughton Jones will, we trust, be productive of great good.

THE IRISH MEDICAL SCHOOLS AND GRADUATES' ASSOCIATION.

THE annual festival dinner was held at the Holborn Restaurant, on March 16th, when a large number of members, and many distinguished guests assembled. The attendance was larger than at any previous meeting of the Society, 120 sitting down to dinner, which was of a most sumptuous character. Dr. Fegan, Blackheath, took the chair, and he was supported by the ex-president, Professor A. Macalister, Cambridge; Dr. Quain, London; Mr. G. A. Sala, Dr. Macnaughton Jones. The Society is increasing in numbers and usefulness, being now 600 strong. It has won for itself an excellent position in the medical world; and by its late action in asserting the claims to equality of Irish qualifications, it has earned the gratitude of all Irish diplomates. We hear that there will probably be a meeting of the Association at Manchester, which we hope will bring a large accession of strength to the Society. The great exertions of Dr. Stewart, who has done so much to the building up of this Association, were justly eulogised by one of the ex-president, Dr. Macnaughton Jones, who has himself done so much to popularize the Association.

THE VOLUNTEER MEDICAL STAFF.

THE exertions of the Volunteer Medical Staff in the metropolis to render themselves efficient, and to promote in every way the welfare of the volunteer medical officers, should incite the extra metropolitan officers to rivalry. Whatever we have won in the way of recognition from the War Office is due, in a very large measure, to a few active members, and the least we can due is to give support to those to whom we owe so much. The Volunteer Medical Association will be pleased to receive fresh members.

WORKMEN'S WEEKLY CONTRIBUTIONS TO HOSPITALS.

IT is no wonder that hospitals are in debt. They are simply managed on uncommercial principles; they try to do too much business on a limited capital, and to give away more than they receive. They invite working men to contribute, offering them all the advantages of free medical advice. The working man contributes a mite, and he expects a return, which he obtains nearly a hundredfold. Hundreds flock to each local infirmary who are well able to pay for private medical advise or assistance. If an official speaks to one of this class, he is told that owing to the subscriptions given advice is asked for as a right, and if it be refused the subscriptions will be withdrawn. In the face of hospital difficulties, money is only too eagerly sought for, and the hospitals, like bankrupts, clutch at the straws by which they hope to be saved from ruin, though they are only sinking deeper into debt, and injuring themselves as well as the general profession.

THE ARMY MEDICAL SCHOOL AT NETLEY AND ITS WORTHIES.

THIS was the subject of an able address by Surgeon-general Maclean, C.B., at the Medical School, Netley. He dwelt upon the work done by Sir Ronald Martin and Parkes, and other worthies who shed a lustre upon the Army Medical Service. The Martin Memorial, he said, perpetuated the name of a man who was cast in a heroic mould, and was one of a service that had produced many men of mark who had faithfully served the State. Speaking of Mr. Parkes, he said, with the science he made his own, his name would be imperishably associated, and the youngest among them knew how well his important work on hygiene was kept up to the highest level of advancing science. In a long life, Dr. Maclean said, it had never been his fortune to meet a man in whom the intellectual and moral faculties were so well balanced as in Professor Parkes. It is thus that the memory of our worthies should be kept green.

A NEW ANIMAL VACCINATION STATION.

DR. WHITESIDE HIME has opened at Bradford a station for the supply of pure animal vaccine; and from a letter received he tells us that:—

"In order to learn the best method for cultivating it I have recently visited the best stations in Belgium, Holland, and Germany, as well as the Government Station in London. The calves are all carefully selected, and are examined and approved of by an experienced Veterinary Surgeon (Mr. J. S. Carter, F.R.C.V.S., Chief Veterinary Inspector under the Privy Council for the East and West Ridings of Yorkshire) before being operated on. The vaccination of the calves, and all the details of the preparation of the lymph, are carried out by myself personally, to ensure the best results, and only lymph which is fresh, pure, and active, is sent out. The source of my lymph is a recent spontaneous case of cow-pox, which occurred at Bouge, near Namur, in Belgium. It has, therefore, never passed through any human subject, and its use precludes the possibility of infection by any disease likely to be transmitted by humanised lymph taken from an unhealthy subject. Lymph from the same source as that which I use is now employed at the Park Vaccinogène (Calf-lymph Station), Brussels, and is supplied thence by the Government to medical practitioners throughout Belgium. I can supply you with the lymph in sealed capillary tubes; dessicated on 'points'; between glass 'squares' hermetically sealed; pulverised (so-called 'Reissner's Powder'); as 'Conserve,' glycerized, or in any other form you may specially desire. Should you wish to use the excised 'pock' (the Neapolitan method) it will be forwarded to you, on a couple of days' notice."

PASTEURIANA.

The latest results of the Pasteurian treatment this year are not satisfactory. The year has opened very badly indeed for the Pasteurians. We gave particulars of three deaths in our last issue (p. 179), and we have unfortunately to again have to add to the list of deaths. Of course we have the plea raised that cases that have died have been very severely bitten. This is the exact truth, and is a very good defence; but more should be added—they are also infected; so that it comes to this, that those who are infected die.

Case IV.—Druaux, æt. fifteen years, of Abbervilliers, bitten on January 7th, 1889. Treated from the 9th till the 28th of January. On the 7th of February brought to the Hospital Lariborsiere. Died of rabies on the 11th of February.

Case V.—Dufort, æt. 72 years, bitten very badly on December 22nd, 1888. Treated from December 25th till January 12th. On February 9th, developed symptoms of hydrophobia, and died on February 15th.

These facts are taken from *L'Union Médicale*, March 9th, 1889.

New Remedies.

Eschscholtzia californica—A number of physiological experiments have been made with this plant, in the form of an aqueous alcoholic extract, first upon animals, and subsequently upon patients in the Cochin Hospital. Dr. Ter Zakariant reports that the plant possesses valuable soporific properties, and is useful as an anodyne in some cases, whilst it does not possess the inconveniences attaching to the use of morphine. These properties appear to be due in part to morphine, and partly to a glucoside and an alkaloid hitherto undescribed, which have been detected in it by Messrs. Adrian and Bardet quite recently. It had previously been observed that an extract of the plant produced an effect in cold-blooded animals which could not be obtained by the use even of large doses of morphine. The plant, which is commonly cultivated in gardens in this country, belongs to the same natural order of plants as the poppy.

Picrotoxin has been the subject of some experiments by Professor Bokai, who finds that it acts antagonistically to morphine on the centres of respiration, and on the spinal cord small doses of picrotoxin being sufficient to prevent the paralysis of respiration caused by morphine, or to remove it when it appeared. The stimulant action of picrotoxin on the vessel-contracting centre of the medulla oblongata was also found to counteract the rapid fall of blood pressure, which forms so serious a symptom in poisoning by morphine. Professor Bokai therefore thinks that it would be the most rational antidote to opium poisoning.

The *meconarceine* which has recently been introduced in commerce, in the form of a yellowish liquid, appears to be a mixture of codeine and narceine, with an acid soluble in ether, but which was not identified. A second preparation, of German manufacture, passing under the same name, or sometimes under that of narceine meconate, consists of a mechanical mixture of narceine and meconic acid, apparently in the proportions to form an acid meconate of narceine.

Phenyl propionic and *phenyl acetic acids* have been tried at the Brompton Consumptive Hospital by Dr. C. T. Williams, with the view of destroying the tubercle bacillus. About four years ago it was found by Drs. Klein and M. Lingard that tuberculosis matter of known infective power steeped in a half per cent. solution of either of these acids was rendered inert, and could be introduced into the tissues of a susceptible animal without any ill-effects following. Twenty patients suffering from phthisis in various stages were treated with phenyl propionic acid by Dr. Williams for periods varying from twenty-eight to eighty-five days. Of these cases thirteen improved, four remained stationary, and three became worse. The dose given was ten minims of an alcoholic solution diluted with one per cent. of water, increased to twenty minims in two ounces of water, three times a day. The medicine did not cause either vomiting or anorexia when diluted with water.

Phenyl acetic acid was similarly tried on nineteen other patients suffering from phthisis, of which number thirteen improved greatly, four deteriorated, and three remained stationary. Those who improved gained in weight, strength, and colour, and the cough and expectoration was diminished. The dose given was ten to twenty minims of an alcoholic solution three times a day, for periods ranging from twenty-one to eighty-nine days, and in no case were any unpleasant symptoms observed. Both these acids are soluble in about six parts of alcohol, and both have an acid reaction, which is stronger in phenyl acetic acid.

Dr. Williams concludes, as the result of his experiments, that these disinfectants given in phthisis promote appetite, digestion, and assimilation, and are well tolerated in considerable doses, and that the use of phenyl propionic acid is likely to be useful in excavation cases, and phenyl acetic acid in cases of tuberculisation.

Salol.—A new use for this antiseptic has been suggested by M. Loewenthal. It has been stated that this antiseptic specially exercises its properties after it has come in contact with the pancreatic juice. He has observed that the cholera bacillus, which is inactive as a poison when cultivated in peptonised broth, becomes active if cultivated in pancreatic secretion. He has pointed out, therefore, that as salol will kill the cholera bacillus in a paste containing pancreatic juice, and as the cholera bacillus probably passes through the stomach without activity, but commences to cause the formation of a poisonous ptomaine when it comes in contact with the pancreatic juice, salol seems the most suitable antiseptic to give them. M. Loewenthal has shown that it is by no means dangerous, as he has taken two five-gramme doses in one day.

Condurango bark has been chemically examined by Professor Kobert, who finds that it contains two or three glucosides and a resin, all of them manifesting the same action. These substances form collectively the condurangin found by Dr. Vulpius. It coagulates when heated in an aqueous solution, even at 40° C., and like albumen, is precipitated from an aqueous solution by sodium chloride. Its action on the central nervous system is decidedly a poisonous one. In small doses it produces symptoms like those of tabes dorsalis in ataxic change of gait. It also appears to act on the peripheral nerves and muscles, at first increasing and then depressing their electric excitability. Loss of appetite, and in the earlier stages a plentiful flow of saliva, as well as vomiting, are constant symptoms in mammals. The poisonous dose of condurangin is about 0.02 gramme per kilogramme of the body weight for carnivorous animals, and about three times as much for herbivorous animals.

Sanguisorba officinalis, in the form of an infusion of the flowers, is highly spoken of in the *Pharmaceutische Post* as a remedy for chronic stomachic catarrh. In a case of a year's standing, which was accompanied with heartburn, a cure was effected by this simple means.

Eserine sulphate is said by Dr. Reiss to be a useful remedy in cases of chorea. He gives it in the form of an hypodermic injection, $\frac{1}{12}$ of a grain being injected twice daily. In a number of cases the cure was effected in five or six days, but it was less successful with adults. It was also found beneficial in tetanus, paralysis agitans, spinal sclerosis, and in a case of hysteria in the male, accompanied by great excitability and a remarkable increase in reflex movements.

Periscope.

I.—GLEANINGS IN MEDICINE.

By W. B. KESTEVEN, M.D.

Accidental Poisoning by Cocaine (*Journal de Medécine de Paris*, February 3rd, 1889).—A child, four years of age, took by mistake for coffee, a teaspoonful of solution of cocaine (about twenty-five centigrammes). No immediate effect ensued, but an hour afterwards she suddenly waked up in distressing anguish, pale face, eyes haggard, breathing irregularly, with a feeling of nausea, pain at the upper part of the chest, sense of formication, and cramps, then a choreic agitation. The child was as if drunk, and was the victim of terrifying hallucinations. M. Moizard saw her two hours after having taken the poison, and prescribed an emetic, which brought away the contents of the stomach. An enema containing fifty centigrammes of chloral was administered, and two hours later another enema, with thirty centigrammes of chloral. The excitement subsided and the patient slept, though during the night frequently disturbed by choreic movements. These gradually subsided, and by the next day the child was in its ordinary condition.

Hereditary Transmission of Saturnism (*Gazette Hebdomadaire des Sciences Medicales de Bordeaux*, February 3rd, 1889).—The following instance of this morbid condition was related to the Biological Society of Paris, by MM. Hermann Legrand and L. Winter. The child was born of parents both of whom were the subjects of lead poisoning. It was emaciated, of a cadaverous complexion, weighed 1,020 grammes, and lived only fifteen days; at the autopsy all the viscera were found diminished in volume and weight. Microscopical examination showed cirrhosis of the liver. Micro-chemical tests (iodine, chromate of potash, and sulphide of ammonium) exhibited the presence of lead in sections of the liver. Six grammes of the liver contained one gramme of the metal. The entire liver weighed forty-five grammes. The kidneys showed interstitial proliferation and epithelial degeneration. This case shows the transmission from mother to offspring of a poison considered generally to be insoluble, producing lesions incompatible with life.

Suture of the Patella (*Le Progrès Médical*, February 2nd, 1889).—At the meeting of the Société de Chirurgie, Paris, M. Vermisson exhibited a patient, æt. fifty-eight years, upon whom he had performed suture of the patella. The fracture occurred in July, 1888. The separation was to the extent of 4 cent. Compression was tried, then the "claw" of M. Duplay. Soon afterwards rupture of the callus happened. Suture was then effected with silver ligature. Cure took place with slight stiffness of the joint. The limb was fixed with plaster, and immobility of the fragments obtained. M. Champonniere stated that he had several times effected suture in cases of fractured patella. The proper treatment, he urged, is immediate suture. At the end of fifty days the patient will walk satisfactorily. There will not then be any consecutive atrophy. The general health, age, obesity, anterior lesions, may furnish contra-indications. Sutures should always be employed when the patient can have them. Fixing the joint M. Champonniere considers to be useless. He employs usually three silver ligatures, with a firm network, capable of firmly holding the fragments, while callus may or may not form.

A Cause of Tetanus (*L'Union Médicale*, February 7th, 1889).—This question has recently been discussed at the Société de Medicine de Paris. M. Abadie taking up the theory of M. Richelot which attributes an equine origin to tetanus, pertinently asked for an explanation of the occurrence of tetanus in countries where horses do not exist? Why, also, M. Abadie observed, is the disease so rare in rural populations where traumatic lesions of all kinds are so frequent, and where the people live in near contact with dung heaps. The doctrine of microbes has not yet solved the question, as observed by the reporter of the discussion. "It did not suffice to show the presence of a microbe in a disease; it must be shown how it take its birth, how it lives, and how it dies." To write the natural history of any of this minute organisms is no slight task, but the progress already made affords hope for the future.

Antisepsis Neonatorum. Dr. A. Epstein (*Centralblatt für Chirurgie*, February 9th, 1889).—Dr. Epstein dwells upon the danger that accrues to both the new-born infant, and to the puerperal parent from neglect of antiseptic measures. The mortality of infants from septic infection, was, Dr. Epstein points out, formerly attributed to spontaneous intra-uterine infection, but this theory must now be abandoned since it can be shown that infection enters the infantile circulation from without. The most frequent point of admission being the umbilical cord, which during the first days is obnoxious to inflammation and ulceration; whilst the remainder of the divided cord is undetached. Other sources, or modes of entrance of infection are the mouth, the genitals, and the accidental injuries to the external surface of the body. To protect the umbilicus Dr. Epstein has employed antiseptic bandages prepared with salicine, iodoform sublimate, in both liquid and dry forms, precautions being observed against the neglect of antiseptics by attendants. Permanganate of potash is added to the first bath for the use of the infant.

Examination of Fœtal Blood at the time of Birth. By D. Scherenziss (*Centralblatl für Gynäkologie*, February 9th, 1889).—The following are the author's conclusions: 1. The fœtal blood has a lower specific gravity than that of the adult. 2. Fœtal blood is deficient in hæmoglobin, and on the other hand rich in stroma. The proportion of the hæmoglobin is to that of the adult 76.8-100. 3. The fibrin of fœtal blood is relatively to the maternal blood at 2-7. 4. The fœtal blood is not suitable for quantitative analysis by diffusion in saline solutions, the elements of the blood-globules, especially the hæmoglobin become disintegrated in the saline solution. 5. Fœtal blood is richer in salts than adult blood; there is a marked preponderance of chlorides and salts in the serum. 6. The fœtal blood has a larger proportion of sodium, and is, relatively, poorer in potassium than adult blood. 7. The quantity of uncombined potassium and sodium in fœtal blood, is notably less than in adult blood. 8. The sex and size of the child do not appear to have any influence upon the quality of the blood at birth.

Hypnotism and Suggestion. By Dr. B. H. Stephan (*Alienist and Neurologist*, St. Louis, January 7th, 1889).—Dr. Stephan gives a cursory glance over the history of hypnotism, mesmerism, etc. We quote his closing remarks:—"It is quite generally accepted that hysteria and neurasthenia are much closer related to psychoses than to organic nervous diseases. That these psychoses in some instances arise reflexly is beyond all reasonable doubt; but in many instances they are brought about more or less directly, and are presumably dependent upon a functional disturbance of the cerebral gray matter. It is against the latter form of psychoses that it is proposed to make use of hypnotism and suggestion; but even in these cases, this method, though often removing symptoms, may not act curatively on the original disease. It is almost certain that neuropathics, labouring under the fixed idea that they are subject to this or that form of disease, often succeed in developing the symptoms properly belonging to it. Neurasthenia is either inherited (this is by no means rare in these days of fast living), or has resulted from the influence of social embarrassments, business reverses, loss of property, pressing cares, disappointed hopes, unsatisfied ambition, family troubles, grief, etc.; and in such a soil, under the suggestive influence of a fixed idea, a functional disorder of some kind has taken root and developed itself; but though suggestion has really played an important *rôle* in originating this trouble, an exclusively psychic treatment, by means of hypnotism and suggestion, will generally have little or no effect, inasmuch as the pathogenic idea has been developed in a soil which remains uncultivated, and in the midst of surroundings and circumstances which do not change; and thus it is that the isolation of the patient becomes a primary necessity in order to give to therapeutic suggestion a chance of permanent success. Isolation—the removal of the patient from the environments in which his troubles began—is one principal resource in the treatment of hysterical neurasthenics. . . . If I should try to give a *résumé* of my opinions, as expressed in what has gone before, it would read somewhat like this:

1. The experimental study of hypnotism deserves undivided medical interest and attention.

2. It is not improbable that in the suggestibility of hypnosis an important therapeutic agent will be found to have been discovered.

3. As there are dangers connected with hypnotism, and as no positive indications for its application have as yet been given, prudence bids us be very cautious in its use.

4. At present there cannot yet be any question as to the applicability of this method to any but dynamic disturbances; but, though the probability is not great, the possibility that even organic affections may not be entirely beyond its reach must by all means be kept in view. Facts, however, are still wanting which may be considered as having positively demonstrated its efficacy in such cases.

Pregnancy in the Rudimentary Horn of a "Unicorn" Uterus (*Centralblatt für Gynäkologie*, No. 5, 1889).—The patient, twenty-nine years of age, had borne three children at the full period. Her last menstruation occurred on the 7th November, 1887. By the month of February the uterus was enlarged, but not uniformly. After the fourth month, by which time it had attained the form of a tumour of about the size of a child's head, violent uterine pains came on, together with

symptoms of internal hæmorrhage. Laparotomy was performed by Professor Slaviänsky. A large quantity of blood was found in the abdominal cavity. Pregnancy had taken place in the rudimentary uterine horn, on the posterior surface of which was a laceration. Hæmorrhage had taken place from a sub-peritoneal vein. The fœtus was of about the usual size at four months. The patient died in four days from general peritonitis.

Chronic Cocainism (*Le Progrès Médicale*, February 2nd, 1889). At the meeting of the Biological Society, Paris, January 26th, M. Magnau read an important paper upon chronic poisoning by cocaine. Instances of acute cocainism have been studied by physiologists on the one hand and by surgeons on the other. Chronic accidents are less known, but present especial features, which are noted in the following cases:

Case 1.—A merchant, æt. forty-eight, had, on account of nephritic pains, commenced the use of morphia in 1878. In order to cure himself of the habit, he, in 1886, commenced the use of hydrochlorate of cocaine, the dose of which quickly reached to a gramme. Symptoms occurred which alarmed him; he suffering from illusions of hearing, jerkings of the limbs, etc. In consequence of the occurrence of these symptoms he resumed the morphia for six months, when he returned to the cocaine, and the hallucinations occurred. He experienced sensations as of blows and pricking on the surface of the body, with diminution of sensibility. In the course of a short time (?) he became epileptic.

Case 2.—A Pharmacien, æt. forty-four, in 1884 was taking morphia for colicky pains. In 1887 he began with cocaine, and became the subject of symptoms similar to the preceding, followed by epilepsy.

Case 3.—A physician, æt. thirty-nine, took morphia for neuralgia, but had no sensorial troubles. In 1887 he commenced with cocaine and reached a dose of two grammes; he then suffered haullucinations of sight and hearing with impairment of cutaneous sensibility.

These three cases show that the action of cocaine is different from that of morphia, and resembles rather that of absinthe or alcohol, with this difference that the poisonous effect of cocaine is exerted upon the cerebral cortex, taking its course from the occipital lobes towards the sensorial centres, the reverse of which obtains with alcohol and absinthe.

Menstruation—Its Nerve Origin; not a Shedding of Mucous Membrane. By James Oliver, M.B., F.R.S. Edin. (*Alienist and Neurologist*, St. Louis, January, 1889).—Dr. Oliver points out that this monthly phenomenon is the result of changes in the condition of the nerve supply, manifested by symptoms of a general character. "With the approach and appearance of the monthly flow the whole frame, as one would naturally expect, participates more or less in the change, and the amount of disturbance experienced as well as manifested is commensurate with the power the organism possesses of adaptation." "The true nature of the catamenial discharge is still conjectural," Dr. Oliver remarks, "yet its elimination from the body renders it highly probable that having already served some special end, its detention in the blood may exert some deleterious influence upon the animal economy." Dr. Oliver doubts that ovulation and menstruation are coincident. "It is alleged," Dr. Oliver further observes, "as an established theorem that from the period of puberty to the climacteric age there is, besides a gradual death of the mucous membrane lining the whole uterine cavity —which must ever recur, to be compatible with life—a more or less regularly-recurring and complete death of this coat. In the whole animal kingdom we search in vain for a physiological change truly analogous with this. . . . I have never at any time detected any evidence of structural change, microscopically, in the inner linings of the uterus in cases in which this organ has been removed from the bodies of females who have died either during or just before an expected menstruation. . . . Taking all the facts into consideration, it is more than probable that the recurring monthly discharge in the human female is a secretion, or rather excretion, from the lining membrane of the uterus and Fallopian tubes, without degenerative change other than that commonly associated with augmented functional activity, and comparable with that occurring in any other organ of the body under similar circumstances."

Intestinal Sutures, with a Report of an Experiment illustrating the use of both the Interrupted and Continuous Sutures. By W. V. Kingsbury, M.D., of St. Louis (*The St. Louis Medical and Surgical Journal*, January, 1889.—Dr. Kingsbury prefaces the report of his experiments by the following remarks: "To unite and retain in opposition the edges of a divided, incised, or lacerated bowel, has been one of the greatest desiderata of surgeons from the earliest period of intestinal surgery down to the present day. How to secure the edges of a wound by the means of sutures, so as to prevent the passage, either outwards or inwards, of any of the solids, fluids, or gases, was, for a number of years, a question which perplexed the minds of surgeons." After having described the proceedings and experiments, Dr. Kingsbury submits the following conclusion: That the interrupted suture is better than the continuous suture for wounds of the intestines whose long diameter extends in the longitudinal direction of the bowel. In making the continuous suture it is necessarily exercised in the longitudinal direction of the bowel by means of which the edges of the wound are approximated; in making the interrupted suture, traction is used only in the transverse direction. It diminishes the calibre of the bowel no more than does the continuous suture, and can be applied with very little more difficulty.

The Treatment of Tabes Dorsalis by Suspension (*Der Fortschitt. Genf.*, February 5th, 1889).—The introduction of this method of treatment is due to Professor Maschoukowsky, of Odessa. The treatment consists in the adaptation of the sitting posture, leaning on a Sayer's corset, to an apparatus by which the patient is suspended for progressive periods from half a minute to four minutes. Eighteen patients were treated in this way, by M. Charcot, in 400 sittings. Of these, fourteen were improved, while in eight the amendment was very noteworthy. The first sign of improvement is seen in progressive locomotion. The lightning pains become less frequent, and gradually disappear. The improvement is gradual, and, in proportion to the duration of the treatment, which is, so far, safe and worthy of extended trial.

The Pathology and Treatment of Purulent Pachymeningitis, connected with Inflammation of the Middle Ear. By Dr. Eg. Hoffmann (*Centralblatt für Chirurgie*, February 9th, 1889).—Dr. Hoffmann, from his own observations, and from the records of cases in medical literature, traces the connection between these two conditions. As the result of 102 *post-mortem* examinations, he found the most frequent lesion in the propagation of the inflammation from the middle ear, inducing abscess of the brain. The pus finding its way by the vascular or nervous canals, and appears externally at the mastoid process. The treatment adopted consisted in the evacuation of the abscess.

Salicylate of Mercury (*Gazette Hebdomadaire des Sciences Médicales des Bordeaux*, February 3rd, 1889).—Dr. Silva Araujo, called the attention of the General Polyclinical Society, of Rio de Janeiro, to the above-named mercurial combination, and pointed out its advantages as follows: 1. It is borne well by the stomach, causing no disturbance of that organ, nor diarrhœa, as frequently occurs with mercurial preparations. 2. It does not give rise to stomatitis. 3. It acts more promptly than other mecurials.

The observations of Dr. Araujo have been confirmed by Dr. Szadek, of Kiew. The dose has been one centigramme, or 0.25 milligramme as pills, three times a day, progressively increased.

Tubercular Cavity in the Wall of the Left Ventricle of the Heart. By Dr. Mariani, Madrid (*Le Progrès Médical*, February 2nd, 1889).—In this case there had been no indication of its presence during life, neither was tubercle found in any other organ. Dr. Mariani states: The patient who had died of uterine affection, had suffered from mitral insufficiency. At the autopsy, on detaching some adhesions which existed between the pericardium and the anterior aspect of the heart, an incision gave exit to caseous matter. The heart was carefully inspected in order to ascertain the source of this caseous matter, and it was not without surprise that a cavity the size of a common nut was found in the anterior wall of the hypertrophied heart, presenting all the characters of a phthisical tubercular cavity. Its anterior wall was very thin; its posterior wall was about eight millimetres in thickness. A microscopical examination of the contents showed bacilli, micrococci, and pus globules, with calcareous particles, and corpuscles of cartilage. The diagnosis of mitral insufficiency was fully conformed by the autopsy.

Iodoform in Diphtheria (*Saint Louis Medical and Surgical Journal*, January, 1889).—In the Polish weekly *Gazeta Lekarska*, No. 36, 1888, Dr. A. Pulawski, of Warsaw, details seventeen cases of diphtheria, mostly of a severe kind, rapidly cured by the local use of powered iodoform, in quantities varying from five to ten grains, twice or thrice daily. The drug was applied by means of a brush or an insufflator. According to Dr. Pulawski, iodoform acts as an antiseptic, and represents, generally, the best anti-diphtherial means of all known. The main advantages are said to consist in: (1) its being absorbed but gradually; (2) in its application being easy and simple; (3) in its manifestation (powdering, insufflator) being free from such danger as wounding the effected mucous membranes.

The Cœloscope (*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, February 3rd, 1889).—Dr. Cæsar Belin has submitted to the Academy of Medicine, a new electric lamp for the investigation of the natural cavities. The construction of the "cœloscope" is based upon the property possessed by a glass rod of transmitting luminous rays without calorific rays. Thus the cœloscope serves to illuminate, but does not heat the mouth, the vagina, the bladder in the supra-pubic sections, and the peritoneal cavity in laparotomy. It consists of a small electric lamp enclosed in a flask, and mounted upon a glass shank of different sizes according to the nature of the cavity to be explored, the operator holding the flask in his hand, and regulating the light by means of a communication with a galvanic pile.

Injection for Gonorrhœa (*Saint Louis Medical and Surgical Journal*, January, 1889).—Signor Turpura Impallomenti states (*Farmaceutic Italiano*) that a 1 per cent. solution of creasote in decoction of chamomiles combined with boric acid will kill the gonococci in two hours. What is more interesting, probably, is his statement that he has cured five out of seven patients in six days.

Idiocy and Feeble-Mindedness in Relation to Infantile Hemiplegia. By William Osler, M.D, Pennsylvania (*Alienist and Neurologist*, St. Louis, January, 1889).—"Hemiplegia," Dr. Osler observes, "is by no means an uncommon affection in children, second only to spinal paralysis in frequency, and much more serious in its consequences. The records of the Philadelphia Infirmary for nervous diseases show that more than one in five cases of severe paralysis in children is of cerebral origin." "The majority of the cases of infantile hemiplegia occur during the first two years of life. The affection sets in suddenly with convulsions, often with fever, then coma of variable duration, and when the child awakens it is noticed to have lost power on one side. This mode of onset occurs in three-fourths of the cases. After a time the paralysis begins to improve; the face first; speech if lost is regained, and power returns to the leg. The use of the arm is rarely regained, and in many cases it wastes. A majority of the patients have the characteristic hemiplegic gait. In time as a rule, a spastic condition develops in the palsied members and in the arm contractures are common . . . More serious consequences follow—many of these children become epileptic, and a considerable number present all grades of mental defect, from a simple feeble-minded condition to the most profound idiocy." Much doubt exists as to the primary lesion in these cases. The pathological conditions that are here enumerated, are: encephalitis of the gray matter of the motor regions. Embolism, thrombosis, sclerosis, porencephalus, and vascular obstrucion. Concise notes of twenty-two cases are given by Dr. Osler.

Responsibility in Inebriety. By T. D. Crothers, M.D., Hartford, Conn. (*Alienist and Neurologist*, St. Louis, January, 1889).—Dr. Crothers discusses this question in all its bearings, and submits the following summary of his conclusions:

1. In all cases of inebriate criminals there is mental defect, and both incapacity to reason sanely or control their acts. An inebriate who does criminal acts cannot be of sound mind. A criminal who is inebriate is not sane. No inebriate is fully sane, and no criminal can be of sound mind long.

2. The question for the medical witness is—how far was the prisoner conscious of the nature of his acts? and how far did he have control over his acts in a certain crime.

3. John Smith has committed a crime while under the influence of alcohol, and the law inquires into his mental condition at the time of the crime. His impaired mental health and responsibility is beyond doubt. Is it possible from a study of the facts in the history of the prisoner, to determine the ranges of responsibility and accountability? Can we go into this penumbra region of sanity and insanity, and follow vice up to the dead lines of disease, and show where human justice should punish, and where it should forgive, as irresponsible?

4. The medical man approaches this problem from the scientific side, seeking the facts beyond all moral or legal theories of brain action. There should be no hesitation in stating what appears to be truth, no matter how far it is beyond the popular intelligence of the present.

5. If the facts in the history of the prisoner point to a degree of unconsciousness of the nature and character of his acts, and the inability to control such acts, the insanity of the prisoner should be assumed as a fact, far more likely to be true than the opposite. The limits of scientific study will not sustain any efforts to draw boundary lines where health and disease join.

6. When the fact of the inebriety of the prisoner is established, his sanity in a given case must be proven and sustained beyond all question or possible doubt. All the circumstances and conditions of the crime and life of the prisoner must bring evidence to prove this fact. The general fact of inebriety reverses the natural order; his insanity must be assumed, and his sanity proven.

7. Finally, in all these cases, the medical witness is called to determine the physiological, pathological, and psychological facts and their meaning. The applications of these facts are for the law, court, and jury.

The medical expert of to-day must go beyond the theories of yesterday, or the facts on which yesterday's views were based. A newer, larger field opens up to-day, and the facts are more numerous, and indicate a clearer, wider view to-morrow.

Why the Bromides should be largely Diluted in Epilepsy (*The Alienist and Neurologist*, St. Louis, January, 1889).—Dr. C. H. Hughes, of St. Louis, states that it is his practice to direct the admixture of each dose of bromides with a glass of water or of milk in order to prevent gastric irritability and to secure rapid absorption, and secure dilution of the blood in order to prevent the thickening which induces spasm of the vessels, and to which, perhaps, is due to the recurrence of epileptic attacks. "Thus: the thickening irritates the vasomotor and psychomotor centres till their irritability is exhausted. The rest, inertia and slumber, after the attack, makes less demand upon the blood than the active state of the individual, until a time is reached after the return of the accustomed demands of waste and repair, when an abnormal disproportion of sanguine liquefaction is reached, incompatible with physiological movement of the vasomotor and psychomotor centres in their normal condition. It becomes impossible for a due amount of nutriment and sustaining pabulum to be appropriated from the blood thus increased in consistency and decreased in fluidity. The non-striated muscles of the arterioles, unsupported and unnourished, take on an abnormal irritability, and contract in spasm. The psychomotor centres, thus rendered anæmic, show their distress in convulsions. A psychomotor centre convulsed is an oppressed centre of motion struggling for its normal equilibrium. The cause of its tumultuous effort is the robbery of its normal support and nutrition, either through decrease of blood quality or quantity, which may result from under-pressure, over-pressure, or toxic states."

Creolin. By Dr. J. E. Lowrey, Denver (*Denver Medical Times*, February, 1889).—Creolin, the new antiseptic, is undoubtedly the best representative of its class. The non-poisonous character of the preparation gives it a great advantage over the older antiseptics. It can be taken internally in large doses without danger, and in this particular it fills a long-felt want. It is a dark brown syrupy fluid, the product of dry distillation of certain forms of English coal. It is miscible with water, but the mixture is not clear, which is one great disadvantage in its use as an antiseptic wash, especially in cavities. The uses of creolin are numerous and important. In obstetrical practice it is destined to replace carbolic acid and bi-chloride, being more efficient than the one and less dangerous than the other. It should be used in a one-per-cent. solution. The result of 280 parturitions equally divided between bi-chloride and creolin showed conclusively the value of the latter, not a single case of severe sepsis following its use. In purulent inflammations in the genito-urinary tract it acts with promptness and certainty, especially in cystitis. As an internal remedy creolin has already established quite a reputation. Administered by inhalation, in pulmonary tuberculosis, especially early, it favours expectoration and diminishes the secretion almost immediately. It has been used with success also in diphtheria and all affections of the alimentary canal, such as meteorism, typhilitis, intestinal catarrh, and especially typhoid fever, and in fact any disease of the stomach or intestines where an antiseptic agent is indicated. It should be given in doses from five to fifteen grains t. i. d.

Dupuytren's Contraction (*New York Medical Journal*, February, 1889).—Dr. Willy Meyer presented at the meeting on December 9th, 1888, an elderly man upon whom he had operated for this condition. He mentioned different theories held as to its causation and the various modes of surgical relief. He preferred, on the whole, the removal of a long strip of the palmar fascia in the line of the contraction, the strip tapering to a point above. Dr. Abbe recommended making a series of sections across the line of contracture, but had also obtained good results from excising a band of the fascia. Either operation could be done in ten minutes under local cocaine anæsthesia. He thought it very important not to put the hand into full extension or over-extension afterward, as it set up a state of excitement in the fascia and caused pain and œdema. The condition was already one of hyperplasia of the aponeurotic structures, possibly due to irritation made liable by the absorption of the underlying cushion of fat.

Enormous Nævi cured by the Galvano-Cautery (*New York Medical Journal*, February 9th, 1889).—At a meeting of this society

(December 9th, 1888) Dr. Abbe presented a child of twelve years whose treatment for nævi of phenomenal size was nearly complete. These had appeared as soft vascular tumours just beneath the skin, at first on the fingers, then on the forearm and arm, and finally about the root of the neck, where, from their size, they became, so to speak, great bags of blood which filled the whole hollow of the shoulder. He had at first treated some of the smaller of these tumours on the fingers by electrolysis, using fine needles, making from fifty to a hundred punctures, and holding the needles inside till he heard the blood bubbling; but this method had not succeeded when used to reduce the larger tumours in the arm. He had had better success with the Paquelin cautery and the galvano-cautery. At the elbow he had cut out one of the tumours, but the hæmorrhage had been such that he had not dared attempt to remove the larger ones about the shoulder. For these he had arranged a device which was, so far as he knew, a new one. A platinum wire had been introduced beneath the skin, carried around the vascular tumour, and brought out again nearly at the point of entrance. Then a strong galvanic current had been sent through the wire, and the loop of the latter slowly withdrawn, burning its way through the vascular mass, and out from the skin between the points of its entrance and exit. It had left but a slight red cicatrix an inch in length where the loop had been withdrawn, and the nævus had been almost entirely reduced. The only other method which the speaker considered adequate for the treatment of large nævi was that recommended by Roser, who drew through the tumour fifty or more threads charged with persulphate of iron.

Male Sterility (*Medical News*, Philadelphia, February, 1889).—Dr. Fürbringer, of Berlin, has written some important observations on this subject in the *Deutsche Med. Wochenschrift*, No. 28, 1888. He believes that sterility in the male is far more frequently the cause of barren marriage than is generally believed to be the case. Aspermatismus is associated with complete impotence, but azoöspermia, or absence of spermatozoa in the semen, a condition by no means rare, may exist with perfect potency, and on that account is very easily overlooked. With few exceptions, azoöspermia is caused by obliteration of part of the seminal ducts. This condition is generally caused by double gonorrhœal epididymitis, or inflammation of the vas. After that malady, the chances are, Dr. Fürbringer has calculated, nine to one that azoöspermia will follow. Prognosis appears to be hopeless when the condition in question is not discovered until three or four months after the onset of the local inflammation. The chief importance of the management of the case lies in accurate diagnosis. True aspermatism is traced by Dr. Fürbringer to arrested development of the ejaculatory ducts. He declares that in several cases of sterile marriages under his own observation the unfortunate wife had been sent from physician to physician, or from hospital to hospital, and her cervix divided, or her endometrium scraped, until a glance at the microscope proved that nothing was wanting to insure the blessing of children, excepting spermatozoa. Dr. Fürbringer's observations are worthy of consideration. No doubt the increase of temperance involves the relatively greater frequency of those forms of gonorrhœa where the earlier symptoms are very mild. Hence the first stages may now be as much neglected by patients as they have ever been wont to neglect later stages. The more a case of gonorrhœa is neglected, the greater will be the chance of serious secondary complications.

Bromide of Gold in Epilepsy (*Philadelphia Medical Times*, February, 1889).—The following extracts are made from the essay of Dr. Goubert, which received the prize of the Academy of Medicine:—The numerous causes of epilepsy have given rise to a variety of treatment, among which that of the bromides deservedly takes the first rank. For many years, bromide of potassium, sodium, ammonium, lithium, calcium, zinc, arsenic, nickel, camphor, ethyl, have variously been employed, but their action appears less reliable than the bromide of potassium, or a combination of three—potassium, sodium and ammonium. In 1878, the author first used bromide of gold, and encouraged by the results, has established a treatment of remarkable activity. The form preferred is the solution, which is of a dark orange colour. The least dose for an adult is eight milligrammes in twenty-four hours; for a child, from three to six milligrammes will suffice. When wishing to obtain a rapid effect in an adult this dose is gradually increased until the effect is obtained. If the dose is increased a persistent headache may occur, which ceases when the dose is lessened. The author has never exceeded a dose of twelve milligrammes. The advantages are the small quantity required, compared to the bromide of sodium or potassium necessary to obtain a good result; and the absence of digestive disturbance renders it possible to continue the treatment for a long time without intermission. No phenomena of bromidism have been noticed; no cutaneous accidents, nor loss of memory, or diminutions in sexual functions. Every one is familiar with the grave result of the bromide treatment upon the general health of epileptics. Bromide of gold is more rapid in its effects, and gives rise to none of these very disagreeable phenomena. Another point worthy of attention is that the effect is lasting, and remains sometimes for many years without other treatment and with no return of the epileptic attacks.

Bandaging the Extremities for Pulmonary Hæmorrhage (*Medical Bulletin*, Philadelphia, February, 1889).—Seitz (*Archiv. für klinische Medicin.*), as the result of experimental investigations, recommends bandaging the extremities for hæmorrhage from the lungs; first the upper extremities, at or about the middle of the arm, then the lower at the middle of the thigh or immediately below the knee, using silk bands about three-fourths of an inch wide, or, in case of necessity, strips of any sort. By imprisoning the blood the tension of the left ventricle is diminished, and contraction of the vessels in the area not included occurs. The half-hour during which the bandages are retained suffices for the formation of a thrombus at the site of hæmorrhage. The method was used in the time of Hippocrates.

Case of Fracture of the Fibula treated with Massage. By Dr. L. Marevéry (*L'Union Médicale*, 14th February, 1889).—The patient, æt. forty-one years, of good health, had a fall on the 22nd November, 1888, and was sensible, at the time, of a "cracking" at the right external malleolus. Reduction of the dislocation having been effected, the existence of fracture of the fibula was evident. The foot was covered with compresses and oil silk, and the limb placed in a raised position. On the following day there was considerable tumefaction about the ankle. On the 24th November massage, with opodeldoc, was used for twenty minutes. A second massage was practised on the 25th. The swelling gradually subsided. Altogether massage was used seventeen times. On November 28th the patient could stand, with slight help. A caoutchouc bandage was applied. This was changed to flannel on December 8th. On the 11th she was able to stand (in nineteen days), and to resume her occupation, forty days after the receipt of the injury.

Case of Creolin Poisoning (*Medical News*, Phliadelphia, February 29th, 1889.)—Dr. Cramer reports the following: a five year old boy, upon whom he had operated for an inguinal hernia, was ordered applications of gauze saturated with a two per cent. creolin solution, the same antiseptic solution having been used during the operation. Everything went on satisfactory, no fever set in, the urine continued clear for three days after the operation; in fact, general condition was excellent. On the evening of the third day, Dr. Cramer was called to the patient's bedside to treat, what seemed to the parents, to be scarlet fever. He found the entire body, including the face and hands, covered with an exanthem resembling scarlet fever; the little patient appeared extremely restless, complained of great thirst, and of an itching and burning of the skin, temperature was normal, pulse somewhat rapid and small. The urine had a strong carbolic acid odour, as well as the characteristic carbolic acid colour.

Dr. Cramer immediately replaced the creolin application by a three per cent. boric acid solution, and administered internally large quantities of seltzer water in order to facilitate the elimination of the creolin through the kidneys. The exanthem lasted until the following morning when it disappeared; but the urine remained dark until the following evening. The boy made a complete recovery.

A Sulphonal Exanthem (*Medical News*, Philadelphia, February, 1889).—Dr. Schotten, of Cassel, reports the case of a delicate, nervous woman, æt. forty-five, suffering from chronic myelitis, who for one year had regularly taken chloral on retiring. On the night of August 29th, this patient was given thirty grains of sulphonal; it did not produce sleep, but rather a sense of extreme fatigue. The following evening thirty grains more were administered, with the same effects. On the third evening forty-five grains were administered. This was followed by a prolonged sleep, but on awaking the patient complained of peculiar feeling of extreme fatigue, manifested by great inclination to sleep, hanging of the head, and difficult motion of the tongue; besides this she complained of headache, of bitter taste, and loss of appetite. This condition lasted four days, after which time an exanthem made its appearance, beginning on the head and gradually extending over the entire body, resembling in form and colour the eruption of measles. The body was hot; the skin had a burning sensation; the mucous membranes were not afflicted. With the appearance of the eruption, the symptoms of fatigue, etc., gradually disappeared. The exanthem lasted two days, after which it slowly disappeared, leaving traces which were yet noticeable on the fourteenth day. A sister of this patient was similarly effected after taking antipyrin.

By G. F. Cadogan-Masterman, M.D.

Epidemic Infantile Pemphigus (*Pemphigus neonathorum*). By Dr. Juan Viñeta-Bellaserra (*Revista de Ciencias Médicas*, Barcelona).—The recent occurrence of three cases of this not very common disease here induces me to give a concise account of its appearance and successful treatment. By pemphigus we understand a disease of the skin, which may be acute or chronic, contagious or not so, and characterised by the formation of blebs or blisters, usually oviform in shape, and filled with a fluid which may vary from clear citron to opaque yellow or (when containing disintegrated blood) dark brown. In size, they vary from that of a bean to a nut, or even a small apple. The blisters may, under favourable circumstances, disappear by simple absorption of their contents, but more generally they are broken, and ulcers or thick crusts result. It is generally seen in three forms:—*P. vulgaris, foliaceus*, and *neonathorum*. The form termed *P. syphiliticus* is really a manifestion of the latter disease, and should rather be called *syphilide ampullosa* than pemphigus.

The form I am now concerned with usually appears at the hour of birth, and generally either on the face or neck of the infant, and with blebs about the size of a bean. It may, however, show itself on any part of the body, with the exception of the palm of the hands and sole of the feet. They grow rapidly, and the base of each is encircled by a ring of intense redness. Unless promptly treated, the primary ampullæ will be succeeded by others, and accompanied by feverish symptoms. They contain a clear straw-coloured fluid, break very easily, and leave superficial ulcers, which may rapidly extend by the formation of fresh blisters at their margin. Occasionally the disease subsides without treatment, but this is rare; generally, if left to itself, the ulcerated areas enlarge by successive crops of blisters. They become purulent, the feverishness pronounced; there is vomiting and diarrhœa; the mouth becomes aphthous, preventing suckling; the child emaciates, and the face assumes that piteous expression one so often sees in athrepsia, with the wrinkled look of a little old man, and death occurs during the first or second week of its existence. A peculiarity of this form of pemphigus is, that it is epidemic and contagious. The serum from the blisters is auto-inoculable, and will readily infect other children with whom it is brought into contact. Its etiology is doubtful: it attacks preferably, as might be inferred, weak and cachectic subjects, but it is not rare to see the most robust attacked by it, and these latter are quickly reduced to a condition of extreme debility. By some observers, amongst whom are Cazenave, Bouchet, and Paul Dubois, it is regarded as specific in its origin; but this opinion is controverted by the fact that mercurial treatment is invariably useless and generally hurtful.

Differential diagnosis: *Pemphigus vulgaris* appears suddenly; the blister is generally solitary, and there is no erythematous ring, and it attacks people of all ages, but is not contagious.

Pemphigus foliaceus has large, soft bullæ, which form thick, scaly scabs, which are easily detached.

Pemphigus neonathorum is a much more serious disease; it appears spontaneously within a few hours of birth, is auto-inoculable, and the clear yellow fluid in the blebs will convey it both to other children and to adults.

Pseudo-pemphigus syphiliticus generally appears on the palm of the hand or the sole of the foot. The fluid quickly becomes purulent, and the areola is copper-coloured. *Treatment:* The child should at once be isolated, and placed amid the healthiest surroundings; and, if it is being fed artificially, ass's milk had better be given. The blisters should be powdered with starch, and protected by a covering of cotton wool; the ulcers coated with vaseline containing 5 per cent. of carbolic acid; and the gastric irritation relieved by chalk or bismuth mixture and starch enemata.

[Two cases of this disease I have seen were most quickly cured by giving two drops of the tincture of perchloride of iron three times a day, emptying the blisters, and applying a little weak ointment of the yellow oxide of mercury.—*Trans.*]

A Case of Prolonged Sleep. A clinical lecture given in the *Hôpital de la Salpêtrière* by Professor Charcot (*Gazette des Hôpitaux*, Paris, January 27th, 1889).—The woman before you has been sleeping now for three days without awaking for a single moment. She is well known here, and I may say in all Paris, and the newspapers have christened her *la dormeuse de la Salpêtrière*. Her prolonged slumber gives us no uneasiness; we know that she will awake some day or the other, and, although her disease is one of the gravest forms of hysteria, there is nothing of gravity in her present condition. In fact, ever since 1875 these attacks of sleep, if we may call them so, have overtaken her. Once she slept for two months, and on one occasion for forty days. It is a singular type of disease which merits your closest attention, for it is one of that most protean of all ailments—hysteria. It is now twenty-six years, when she herself was twenty-seven years old, since she first entered this hospital, and her history gave these significant data: mother an epileptic in her childhood; father a drunkard, probably a dipsomaniac; sister extremely "nervous." At eighteen years the patient had for the first time an hysterical attack; and you see the tenacity of a morbid condition which many medical men still regard as a trifling disease. The fits of struggling lasted until 1875, when they were replaced by, shall we say, fits of sleeping. The former attacks were of the class we conventionally call hystero-epilepsy, but they have nothing in common with the *morbus sacer* except the convulsive movements which simulate it.

This unfortunate woman suffers from another disease which not unfrequently follows prolonged hysteria—paraplegia. It is sometimes recovered from, but it will not be so in this case. Look at the atrophied muscles, the limbs wasted to skin and bone, the twisted feet, and you will not have to ask me if this poor creature can ever be the better for the treatment she will receive from us. The condition in which you now see her we call an attack of sleep: but can we really call it so? In any case it is not natural sleep. When one is sleeping a loud noise will awake, or applying ammonia to the nostrils, or the electric shock restores one to immediate consciousness. Our patient is not in the least disturbed by either of them. The only thing which affects her is compression of the ovary, and then she only groans and slightly moves, but does not awake. And yet, in spite of this deep apparent sleep, she does not lie motionless as a healthy sleeper would. A wave of contractions passes from time to time over her body; there is that quivering of the eyelids which is so pathognomonic; her limbs contract, and occasionally she raises her body to make a kind of half salutation. All this tension and agitation is so entirely different to the repose and muscular relaxation of true sleep that they lead me to consider this somnolent condition to be an aborted fit of hysteria—an attack which prostrates in place of exciting the storm of convulsive movements we usually associate with it. This apparent calm should not deceive us, however, it is the death-like silence which precedes the fury of a cyclone, not the slumber of the summer seas.

This contraction of the muscles of the extremities, that foam on her lips, are not epileptic, but, with the occasional harsh cry, the disordered movements of the body, are but arcs of the complete circle of an attack of hysteria. From some slight exciting cause this troubled sleep could at any moment pass into the shrieks and convulsions of the classical attack.

But you may ask me, Why do not these symptoms indicate epilepsy? In that disease there are conditions very similar, it is true; but the cause, the mechanism, and the results are entirely different. One observation alone is sufficient to decide the question. The thermometer tells us that in epilepsy there is enormous internal combustion going on with the development and waste of the energy due to it. But in hysteria the thermometer remains at the normal point, nutrition and metabolism are in balanced relation, or may be both reduced to the condition of the hybernating animal before you. In one case only did I find a considerable elevation of temperature, and anxiously sought the cause: it was simply that the bowels had not acted for several days, and a purgative extinguished it. Again, epilepsy is often fatal; hysteria never.

There is here, also, another fragment of the neurotic circle: cataleptic attitudinizing, which shows the intimate connexion, or rather the common parentage, of hysteria simple, of this abnormal sleep and hypnoticism. How does she live? In the simplest manner possible. They get her to swallow a little milk, and that, little as it is, supplies all she needs. In fact, in her present state, nutrition is reduced to its lowest point. There is some emaciation due to autophagia, but it is of no moment, and as soon as she awakes the increased excretion of urea shows how rapidly the function is resumed. This condition can, surely, never be mistaken for the coma of apoplexy. Dr. Devobe has, indeed, called it hysterical apoplexy, but that is a caprice of nomenclature we can well spare.

There is a sudden contraction of the limbs sometimes felt, to their owner's great surprise, by the magnetizers of our boulevards and salons, which is another hysteric fashion which our patient is showing, and it shows too how dangerous it is to play with edged tools. But you must be able to recognize them all. To mistake an hysterical symptom for a grave disease may possibly do no harm to the patient, but it may be extremely prejudicial to the doctor.

Are Sewage Farms a Source of Danger to the Public Health? (*Journal d'Hygiène*).—The opinion is almost unanimous amongst sanitary engineers that the best means for dealing with the sewage of a large city is the construction of a perfect system of sewers. There can be little or no doubt about it; but the difficulty

is, what shall we do with the enormous volume of fœcal matters the sewers discharge? When it can at once be sent into the sea, there is a simple solution of the problem: the salt water destroys all the more dangerous agents present with great rapidity, and the extreme dilution renders all poisons innoxious. But few large cities are placed close to the sea; and, if a river be used as the recipient and carrier, unless the volume of sewage be very small relatively to that of the stream, we poison its water, and only distribute amongst other communities the venom we are discharging from our own. It is this latter consideration which has determined the French Government to forbid the opening of the Paris sewers into the Seine, whilst the enormous quantity of sewage to be dealt with renders any system of chemical precipitation impracticable. There remains two plans: to construct a cloaca from the city to the coast, or to distribute the sewage over the plain of Gennevilliers by a system of farm irrigation. Then the question arises: is there any danger therein from the myriad disease germs the sewage must contain? And this point has led to the most acrimonious discussion. Chief amongst the disputants have been Pasteur and Cornil—the former urging the construction of a main sewer to the sea; the latter, farm irrigation, and their diverse views of microbian dangers may be thus summarised:—

Cornil.	Pasteur.
We cannot believe that microbes retain for any length of time their primitive virulence. Even when placed in cultivating media, they become innoxious at the end of a few weeks or even days. The only forms which retain any activity are those which have the property of forming encapsuled germs. And pathogenic organisms exposed freely to the oxidising action of the air, and especially to that of the nitrificating microbes, must be rapidly consumed. Light, and, above all, the direct rays of the sun, act in the same way. Arloing showed that it was only necessary to expose the bacillus of carbuncle for less than an hour in full sunlight to render it harmless.	Yes! but we can. Few microbes have been studied from this point of view, but those of carbuncle we know can preserve their infective powers for a long time, even for years.
2. And we must not forget that in the sewers saprogenic microbes altogether outnumber the pathogenic; and it is believed that the former will bring about the destruction of the disease germs floating with them.	2. Certainly not, they do not all die; for there are diseases even amongst which these germs can live. This is the base of the new theory of disease; and, as they exist, they are ever a source of danger, of the very danger we wish to avert.
3. Carbuncle is a disease which gives rise to the formation of encapsuled germs, and yet it is one of the rarest of diseases in Paris: there was not a single case in 1886, and only five in 1887.	3. Carbuncle may be rare, but that is not in question. The point is, that its germs are most permanent, that they may be buried deep in the ground, and then, after having been brought up to the surface again, be as virulent as ever. This fact, of which we have ample demonstration, contradicts the old opinion that burying animals dead from disease will render their remains harmless, and that the carbunculous blood can be safely used as a manure. It has been proved that the germs of typhoid fever will retain their activity for at least five months after they have been buried in the earth at a depth of from thirty to fifty centimètres (Dr. Grancher).
4. One of the most beautiful discoveries of Pasteur is based on the discovery that the poison of fowl-cholera is changed into preventive vaccine by the action of the air. And this action, if evident in the test-tubes of the laboratory, should be greater still in the open fields.	4. Quite so, if one treat of microbes which have not formed germinal spores; but not so when germs or spores which can exist in the air are in question. I have found the germs of carbuncle quite active after having been kept for a long time in a tube simply stopped with cotton wool, and not in any medium.
5. If one bury an animal which has died from carbuncle at a sufficient depth, without skinning it, or spilling any of its blood on the surface, it has no danger whatever for animals pastured above it.	5. This is a profound error: the carbunculous blood escapes from every natural aperture, and if there be any trace of air in contact with it, the germs or spores are produced, and worms or beetles may bring them to the surface.
6. If the objections of Pasteur are founded on fact we might just as well forbid the use of all fœcal matter in the cultivation of our fields and gardens, as well as its use in irrigation. Every heap of dung from the streets, and vegetable refuse from the dustbin would be equally dangerous.	6. How many times have the dejections of typhoid patients, carelessly thrown over gardens, been the cause of the extension of that disease!
7. The excellent sanitary condition of Ginnevilliers, and of other places where sewage irrigation is employed, cannot be denied.	7. It has been proved that typhoid fever—to narrow the issue to a single point—is not endemic in Ginnevilliers; had it not been so, the system would have been condemned long ago. But it does occur there, and the disease cannot appear unless its germs are precedent. "But," it is said, "the disease should be most prevalent where there is more permanent diffusion of these germs." I should not venture to say so. I believe that when people are constantly exposed to the reception of minute quantities of these germs, they become gradually accustomed to them—they are vaccinated—in the same way as the staff of an hospital is almost proof against the attacks of the surrounding diseases. But I should view with terror the replacement of the actual population of Ginnevilliers by another which had not been so seasoned, which had come from a healthy district. I believe that the disease would overwhelm them. And I do not think the doctors will contradict me.

And now, what ought we to do? Should we follow to the letter the advice of the hygienists founded on a science which has had so few years of existence, and does not by any means receive general acceptance? If we are to do so we must drink no milk until it has been boiled; no water until it shall have passed through a perfect and perfectly new filter. We must not eat fresh butter, and only doubtfully the salted; nor fruits which grow near the surface of the ground, such as strawberries, nor fruit of any kind without previously carefully washing it. We must never venture to eat a cherry or an apple which has fallen to the ground, and never walk in the streets without covering the whole of the face with a layer of sterilized cotton wool. Life would be tolerably safe under these conditions, but few people would be so enthusiastically scientific as to think it would then be worth the living.

The French Government has accepted the advice of M. Cornil, but it is to be feared that financial rather than hygienic reasons inclined the balance in his favour.

III.—NOTES FROM RUSSIAN AND POLISH JOURNALS.

By Valerius Idelson, M.D., Berne.

On the Action of Saline Cathartics.—In the Polish weekly *Gazeta Lekarska*, Nos. 5 and 6, 1889, p. 87, Dr. Henryk Kucharzewski (pron. "Kookhajevskee"), of Warsaw, details his very interesting experiments undertaken in Professor I. I. Tümas's pharmacological laboratory, in order to elucidate the cause of purgative effects following the internal administration of neutral salts (saline cathartics). The experiments were conducted on healthy rabbits, having an equal weight, and remaining under as identical as possible vital conditions. In rough outlines, the following method was used:—For four days preceding the experiment no water was given to the animal, but from fifty to seventy grammes of a 0.7 per cent. solution of chloride of sodium were injected under the skin every day. On a fifth day, fifty or sixty grammes of a 15 per cent. solution of sulphate of soda (Glauberian salt) were introduced into the animal's stomach by means of a gastric sound. Seven

or eight hours later the animal was killed, its abdominal cavity opened, and the intestinal contents carefully collected, weighed, completely dried at 60° or 70° C., and again weighed (to determine the amount of fluid in the contents, as represented by that or this difference between the two weighings). In all, four series of experiments were carried out, in each of which one or two animals were left without the salt (for controlling purposes), all other conditions being equal. In the first group of the experiments, conducted in the way just indicated, the *post-mortem* examination of those rabbits to which $NA_2 SO_4$ had been administered revealed very vivid peristaltic movements, and a considerable quantity of fluid (from 86 to 135 grammes) in the large bowel; while in the control-animals the peristalsis was sluggish, and the intestinal contents were almost dry, the proportions of fluid varying between seven and twenty-five grammes. In another series, the hepatic and pancreatic ducts were tied before the administration of the saline solution. In a third, the administration was preceded by the hypodermic injection of atropia in mild toxic doses (in order to inhibit the secretion of the intestinal glands). And in the fourth group, both the ligature of the said ducts and the atropinisation were resorted to. Under all the conditions the results remained identical—that is, the intestines of those animals which had received sulphate of soda were invariably found to contain by far more considerable quantities of fluid than those of the control-animals (in the former the quantity oscillated between 66 and 148 grammes; in the latter, between 16 and 34). The general conclusions drawn by Dr. Kucharzewski from his instructive researches may be summed up thus: 1. Considerable quantities of fluid appearing in the intestinal tract after the internal administration of saline cathartics cannot possibly be attributed to anything like an increased secretion of the bile, or pancreatic or intestinal juice. 2. The increase in the fluid results from an intensified transudation of water from the intestinal vessels (as Liebig thought and taught, and Hay, Brieger, etc., subsequently found). 3. The mechanism of the purgation brought about by saline cathartics is this—"a profuse flow of water from the intestinal vessels gives rise to a corresponding liquefaction of fæcal masses, while an increased peristalsis, caused in a reflex way by irritation of the intestinal mucous membrane, necessarily promotes the excretion of liquefied fæces." [That an intensified peristalsis plays an important part in the purgation from neutral salts has been pointed out by many predecessors of the author, especially by Buchheim, Aubert, Radziejewski, etc.]

Blisters in Nervous Affections.—In the *Vratch*, No. 4, 1889, p. 95, Dr. P. I. Ermakoff, of St. Petersburg, says that Professor Petr I. Uspensky successfully resorts to blisters in cases of headache (in the region of the great occipital nerve), giddiness, cardiac palpitation and intermittency, pains and weakness about the upper limbs, visual disturbances, and such-like nervous symptoms depending upon a diseased state of the medulla oblongata and its neighbourhood. The phenomena are always accompanied by a marked tenderness of the first or second cervical vertebra, usually localised about the transverse process corresponding to the side on which the said symptoms are observed. A persistent application of Milanese blisters to the tender vertebra is usually followed by a striking improvement, or even complete and permanent cure. Dr. Ermakoff adduces six cases where recovery ensued after the application of from four to eight consecutive blisters in the course of one and a half or two months.

Poisoning by Nitro-benzine.—In the St. Petersburg monthly *Vestnik Obshtchestvennoi Hïghieny, Südebnoi ï Praktïtcheskoi Meditzïny*, January, 1889, p. 37, Dr. Serghei N. Iakovleff, of Simbirsk, details a rare case of poisoning with nitro-benzine (or nitro-benzol), ending in death. The case refers to a brewer, æt. thirty-two, of drinking habits, who, when in an inebriate state after a meal, swallowed a large amount of the so-called "essence of myrbane," or "artificial essence of bitter almonds," which he had mistaken for spirits. Shortly afterwards, he was found by his mates lying on the ground, speaking incoherently and suffering from violent retching. He died before the arrival of a doctor (who had been fetched at once). The *post-mortem* examination revealed a pronounced *rigor mortis*, numerous and extensive purple cadaverous stains all over the body, dark fluid blood in the right cardiac cavities and systemic veins, intense venous congestion of the cerebral meninges, with distension of the cerebral sinuses, intense injection of the gastric and duodenal mucous membrane, and a strong odour of bitter almonds, pervading all organs of the body. In view of the smell, the doctors who had performed the forensic examination arrived at the conclusion that they had to deal with a case of poisoning by hydrocyanic acid. A careful chemical analysis of the viscera, however, made by Dr. Iakovleff, established beyond any doubt the fact that the man had died from the ingestion of nitro-benzine. A crucial proof was furnished by Dragendorff's reaction (*Pharmaceut. Zeitschrift fuer Russland*, Year II., p. 232), which is based on the fact that nitro-benzine, when coming in contact with hydrogen *in statu nascendi*, immediately transforms into aniline. Having obtained by distillation of triturated viscera an oily fluid, the author dissolved the latter in a 60 per cent. alcohol, and added to the solution some metallic zinc and sulphuric acid to expose the mixture to the action of heat. After the gas had ceased to develop, he mixed the fluid with carbonate of soda, separated the precipitate (carbonate of zinc) by filtration, and treated the filtrate with ether. On evaporation of the ethereal extract, a brownish oily fluid was obtained, which had a characteristic smell of aniline, and on being mixed with diluted hydrochloric acid and a solution of chlorinated lime assumed a bright violet colour; while, on being mixed with sulphuric acid and bichromate of potash, it was stained in a beautiful rich blue one.

Professor Boehm has been able to collect from international literature only forty-five cases of poisoning by nitro-benzine, of which fifteen ended lethally. A case ending in recovery has been recently published by Dr. R. P. Rostoshinsky, of Tambov (*Proceedings of the Tambov Medical Society*, No. 7, 1888, p. 209. A detailed report may be found in the *Philadelphia Medical and Surgical Reporter*, December 22nd, 1888, p. 784). According to Dr. Rostoshinsky, nitro-benzine belongs to the group of asphyctic poisons—that is, it acts before all on the red blood-corpuscles, destroying their power of absorbing oxygen (partly through the formation of aniline, and partly through the action of NO_2). The respiration is affected before the cardiac action. Any nervous phenomena are said to be of a secondary nature, and to depend upon a disturbance in nutrition of the nervous system, resulting from an abnormal composition of the blood. A fatal case of the poisoning has been described also by Drs. Potekhin and Olenin, of Tambov (*loco cit.*, 1871, No. 8).

On Treatment of Gleet.—At a recent meeting of the St. Petersburg Naval Medical Society, Dr. Alexander L. Ebermann has read an instructive paper (*Meditzinskïa Prihavlenia k' Morskomü Sbornikü*, January, 1889, p. 67) on "Treatment of Gleet," in which he emphasizes mainly the following points: 1. A rational treatment of gleet is unattainable without the aid of an endoscopic examination. 2. Urethral hæmorrhage, accompanying sometimes the use of the endoscope, can be controlled best by a strong solution of nitrate of silver (one drachm to an ounce of water), which is to be introduced on a piece of cotton-wool, through the endoscope. The procedure causes but a slight discomfort to the patient, and that for not more than a quarter of an hour. 3. The examination reveals the presence of small-sized isolated or grouped nodules, with a yellowish central top, which are scattered along the whole canal backwards from the navicular fossa, being separated from each other by intervals varying from one to two centimetres. The nodules are nothing else than hypertrophied mucous follicles, with purulent or mucoid discharge about the outer termination of their ducts. The morbid condition constitutes the most common cause of obstinate chronic gonorrhœa, as is proved by Dr. Ebermann's collection, consisting of 400 virile members. 4. The best plan for removing the lesion and curing gleet itself is to inject into the urethra a solution of iodide of potassium (three grains) in water (one ounce), with tincture of iodine (two or three drops). The injections should be made two or three times daily, the patient lying on his back (on each occasion), and retaining the fluid in the urethra until the appearance of some unpleasant local sensations. The treatment is said to be followed by excellent results, in two or three months, even in most intractable cases of gleet.

IV.—NOTES FROM FRENCH JOURNALS.

By H. R. Hatherly, M.R.C.S.

The Manufacture of Chemical Matches (*Le Progrès Médicale*).—M. Brouardel has been requested by the Health Council to report to the police department on the phosphoric necrosis which has attacked several of the workmen employed in the manufacture of matches. The manufacture includes three dangerous processes: the preparation of the paste, the dipping, and the drying. It is always the phosphorus which is the source of danger, either by its fumes, or by its volatile acids, or by phosphuretted hydrogen. Phosphoric poisoning rarely occurs in an acute form, but is very frequent in the chronic form. In addition to digestive and respiratory troubles, and to nervous and cutaneous symptoms, the truly characteristic feature is what the workmen call *mal chimique*, and which consists in necrosis of the jaw bones. In order to protect the workmen from these forms of poisoning strict regulations have been laid down, and, generally speaking, they are carefully observed. Machinery has, as far as practicable, been substituted for manual labour. Great attention is paid to hygiene, especially in the matter of ventilation. Placards containing plain instructions are abundantly pasted on the walls and work tables. Eating in the workshops is absolutely prohibited. Vessels containing turpentine are distributed

for use. All workmen are enjoined on leaving the workshop to wash the face and hands, and to rinse out the mouth with a wash provided for them. The company also employs a dentist to examine the mouths periodically. M. Pouchet comments on the difficulty in obtaining the co-operation of the workpeople in regulations which they are apt to consider vexatious and an infringement of individual liberty. Those employees who are afflicted with necrosis owe it to their carelessness, want of cleanliness, and nearly always to their own misconduct. If the instructions, however, are strictly observed, they appear to be insufficient, as in spite of them several workmen have suffered from phosphoric necrosis. M. Brouardel advises that the dental inspections which take place at intervals of six months should be made every month. The white phosphorus which enters into the composition of the inflammable substance, communicates to it poisonous properties, which may lead to serious or criminal accidents. Red or amorphous phosphorus ought to be substituted, which possesses none of the dangers incidental to the use of ordinary phosphorus, is not poisonous, and with which matches of excellent quality can be made. The use of amorphous phosphorus is uniformly adopted in Sweden, Denmark, Saxony, Holland, Peru, and Switzerland. The Danish law, which has worked very satisfactorily, is as follows :—

Article 1.—From the 1st of January, 1875, it is prohibited in this country to manufacture any matches containing white phosphorus, or other matches than those which are intended to be struck on material specially prepared for that purpose. It is also forbidden after the 1st July, 1875, to introduce into the country, or sell, matches of which the manufacture is thus prohibited.

Article 2.—In match factories where red phosphorus or hydrochloric acid are used, the place in which the phosphorus is prepared must be well separated from that in which the acid is prepared.

Article 3.—Infraction of this law will be punished by a fine of from twenty to two hundred crowns, and the confiscation of the forbidden matches. These questions will be deemed police questions. Those whom the law concerns are required to regulate their business accordingly.

Whatever precautions are taken in the manufacture of matches, accidents will sometimes occur, but the substitution of amorphous for white phosphorus will entirely prevent criminal poisoning or that incidental to the trade, and also obviate the danger of fire.

Etheromania (*Le Progrès Medical*).—Etheromania is one of the modern forms of alcoholism, and has become so prevalent in Ireland that an association has been formed with a view to placing the sale of ether under important restrictions.

New Spirometer (*Polytechnique Médicale*).—Several instruments have been devised for the purpose of measuring the amount of air expired accurately. Such are the spirometers of Hutchinson and Schnepf, constructed on the same principle as gasometers, that of Boudin, and the pneumatometer of Bonnet, the pneusimeter of Guillet, constructed after the pattern of anemometers, etc. To this list must now be added an instrument which has been invented by M. Ch. Verdin, and which deserves attention, from its relatively small bulk (being easily portable) and for its great precision. Its construction is on the principle of dry gas meters, which possesses the advantage of eliminating all liquids, and renders the apparatus more easy to manipulate and carry about. It is a decided improvement on the spirometers previously constructed after the principle of meters containing water. M. Verdin's spirometer is very sensitive, and is as accurate as need be wished. The slightest breath, even when the tube is some centimetres away from the mouth, is registered. When a slow, steady expiration is made, the indications given by the instrument are absolutely exact; when blowing strongly a slight error is produced, which, however, need not be taken into account, as it never exceeds 1.20 per cent. of the total quantity of air expired. The instrument has three dials, on each of which a hand moves. The large dial marks centilitres, the two smaller ones register decilitres and litres.

Naphthalin in the Treatment of Fœtid Diarrhœa (*Journal de Médicine de Paris*).—Holsti has exhibited naphthalin in intestinal catarrh with fœtid excretions. The dose for adults is half a gramme four or five times a day, but the treatment should not be continued beyond from ten to fourteen days. For infants between one and two years of age, 0.12 to 0.18 grammes four times a day will be found sufficient. In all cases, infants as well as adults, improvement was noted from the commencement of the treatment; occasionally a relapse takes place, the continuation of treatment notwithstanding. M. Holsti recommends naphthalin particularly in cases of chronic enteritis, when other treatment has failed. He has never observed any injurious effects on adults, but a child, æt. one year and a half, who was taking 0.12 grammes of naphthalin four times a day, acquired a serious anæmia. For this reason, Holsti advises watchfulness when this remedy is prescribed for young infants, especially when the remedy is persevered with. In two cases he failed to derive benefit from this treatment

Electrolysis in Stricture of the Œsophagus.—Dr. Dujardin-Beaumetz has treated a case of stricture of the œsophagus successfully by electrolysis, and the patient was present at a meeting of the Academy of Medicine. It is a new application of the principle which has been so successful in the hands of Dr. Fort, for treating stricture of the urethra.

The Transmission of Infectious Diseases from Mother to Fœtus (*Le Progrès Medical*).—It is in the present day an acknowledged fact that disease may be transmitted from the mother to the fœtus, and Dr. Netter has reported a case in which acute pneumonia of the right apex was thus transmitted. A woman in her sixth pregnancy was suffering from pneumonia, and was confined of a seven and a half months' child, which lived five days, and then died without showing any physical signs of pneumonia. The *post-mortem* revealed a true pneumonia of the upper right lobe, double fibrinous pleurisy, pericarditis, cerebro-spinal meningitis with suppurating otitis, and a yellowish clot in the right side of heart. A bacteriological examination demonstrated the presence of Frænkel's microbe. The rarity of pneumonia at this age, and the infective form of this attack, prove that the mother must have infected the child. Dr. Netter has found in mice the placenta, and the blood in the heart of the fœtus, to contain pneumococci after the inoculation of the mother, and Foa and Salvoli have established the same fact with rabbits. In women, Dr. Netter has seen three other instances in which pneumonia of the mother, was present also in the newly-born child, and he believes that the reason that these cases do not occur more frequently, is that the infective pneumonia becomes translated into allied affections.

Calculous Cholecystitis (*Le Progrès Medical*).—Dr. Latouche has recorded a case of cholecystrotomy, in which eighty-four gall stones were removed; the patient survived the operation two months. The case was that of a woman æt. forty-two, who had suffered for some months from a tumour in the right hypochondriac region. About eighteen months previously she had a severe attack of hepatic colic, lasting several hours. The general health was good, and the tumour did not extend beyond the median line, but extended far backwards. It was thought to be a hydatid cyst, and a puncture was made with Potain's apparatus, when 250 grammes of bile escaped. A short time afterwards laparotomy was performed, and a distended gall bladder, surrounded by dense false membranes, was revealed. Eighty-four gall stones of various dimensions were then removed, and after thorough exploration, the cavity was washed out, and drainage was provided for. Temperature 37.8 centigrade, pulse rather rapid. For six weeks there was no unfavourable symptom, but then jaundice suddenly appeared with a great increase in the size of the liver, and the patient died two months after the operation from some obscure hepatic disease.

An Almond in the Right Bronchus (*Le Progrès Medical*).—Dr. Jalaguier reports a case in which the almond contained in a sweetmeat found its way into the right bronchus, and there remained five days. Tracheotomy became necessary owing to laryngeal spasm on the fourth day, but it was only on the fifth day that the foregn body could be extracted.

Births in Paris (*Le Progrès Medical*).—Between the 3rd and 9th March, 1889, 1,253 births were registered in Paris, of these 667 were boys and 586 were girls. Nine hundred and two were legitimate and 351 illegitimate. Not quite a third of the male children born were illegitimate; whilst very nearly a half of the girls were born out of wedlock. It would be interesting to know whether this discrepancy is accidental or constant.

Salol in Infantile Therapeutics (*Journal de Médicine de Paris*).—Salol has been employed by Demme in four cases of articular rheumatism, in two cases of acute endocarditis, and in two cases of vesical catarrh, besides which he has prescribed it for external use in two cases of burns. Two children, æt. eight and fourteen, suffering from acute rheumatic polyarthritis, were given in twenty-four hours 2·40 grammes of salol, and the treatment was continued for five days in one case, and for seven days in the other. As the temperature diminished the daily dose was reduced to 1·44 grammes. Salol does not act rapidly, the disease lasting about fifteen days, but on the other hand there is no relapse. A girl, æt. seven, also the subject of rheumatism took, with intervals, as much as 3.35 grammes of salol. In forty-eight hours the temperature was reduced from 39.8° to 37.2° C.; at the same time the pain decreased considerably as well as the swelling of the foot, right knee, and left elbow. In another case, that a girl, æt. nine, salol did not do any good; its administration was

followed by sickness and an eruption of urticaria appeared in eight or ten hours; there was no change in the condition of the joints or in the degree of fever. Salicylate of soda was substituted, and in eight hours the symptoms had subsided, but a relapse shortly followed. Antipyrin was then ordered (3.35 grammes), and after four days health was re-established. In endocarditis, salol proved beneficial when the pulse was influenced by digitalis, and in a case of cystitis caused by cantharides, it also acted favourably, the pain was diminished, the urinary secretion increased, and the alkaline reaction, and muco pus disappeared. Towards the close of the treatment the urine became of a green, brown colour, similar to that which results from phenic acid.

Catholic Faculty of Medicine at Lyons (*Gazette Hebdomadaire des Sciences Médicales*).—A second subscription list, amounting to 225,000 francs, has been added to the former one of 400,000 francs, and a further list has been promised, and will shortly be published. The funds necessary for the construction and maintenance of a first hospital are now provided.

Abridged Dictionary of Physical and Natural Sciences, by Felix Alcan (*Gazette Hebdomadaire des Sciences Médicales*).—The work supplies a gap in the libraries of those who are unable to purchase larger dictionaries, and will be useful to all those who are interested in science, or who read scientific books and journals, or the transactions of learned societies. Readers are often puzzled by technical terms which are not found in general lexicons. It will also prove very useful to foreigners, as the dictionaries of two languages do not contain the explanation of many scientific words.

The Spirit of the Societies.

Nottingham Medico-Chirurgical Society (H. Handford, M.D., president.) **Infantile Scurvy.**—An admirable address was delivered by Dr. Thomas Barlow, of London, on infantile scurvy, and its relation to artificial feeding; he showed numerous pathological specimens, photographs, drawings and diagrams, illustrating the subperiosteal hæmorrhages, and other conditions characteristic of the disease.

Acute Tetanus.—Dr. Enoch Snell read notes on a case of this disease which terminated fatally twenty-three hours and a half after the first appearance of trismus and vertigo. The patient was a builder, æt. twenty-seven, and had a syphilitic history. The only discoverable wound was a small sore over a node on the left shin. The last visit was paid about nine hours before death, and up to that time there was no perceptible elevation of temperature. Death was entirely due to tonic spasm of the muscles of respiration.

Treatment of Empyema.—Dr. Kingdon read a paper on the treatment of empyema, and showed several cases which had been cured by free drainage and irrigation in the Nottingham General Hospital.

Dr. Elder showed specimens of (1) large ovarian cystoma; (2) inflammatory uterine appendages; (3) left ovary, with ruptured ovarian artery—all successfully removed from patients under his care in the Samaritan Hospital.

* * * *

Clinical Society of Manchester (Leslie Jones, M.D., president). **Constitutional Syphilis.**—Dr. Simpson showed a boy nearly fourteen years of age who had suffered from constitutional syphilis for several years. There was destruction of the soft palate, with contraction of the faucial opening, and complete destruction of the tongue. There was great difficulty in obtaining any light on the origin of diseases, but what history there was pointed rather to acquired than congenital syphilis.

Spina Bifida.—Dr. Stanmore Bishop showed a case of spina bifida.

Massage.—Dr. Wahltuch read a paper in which, after a short historical review, he explained and demonstrated the various manipulations in massage. The whole paper will be found in our Original Communications, page 220.

* * * *

Manchester Medical Society (James Ross, M.D., president). **Laryngeal Polypi.**—Dr. Thomas Harris exhibited a woman, æt. forty-three, who had suffered from almost complete aphonia since she was thirteen years old. When first she came to Dr. Harris the larynx was full of polypi, only a small aperture existing at the posterior part, through which the patient could breathe. He had removed the greater number of growths with the laryngeal forceps, and proposed to destroy the two remaining growths with the galvanic cautery. Microscopical examination showed the growths to be simple papillomata, which had a very thick covering of squamous epithelium, the surface layer of cells being very closely packed together, just like a hard warty growth of the skin. The case was also interesting in consequence of the long duration of the growths. It was probable that they had existed twenty-one years, but had never been diagnosed until a few months previously, when a laryngoscopic examination was made for the first time. The patient was in a moderately good position, and had been under treatment repeatedly for hoarseness and difficulty of breathing.

* * * *

Medical Society of London (Sir William MacCormac, president). **Ulceration of the Tongue cured by Opium.**—Mr. Shield showed a man, fifty-six years of age, who had suffered for three years from obstinate ulceration of the sides of the tongue and gums, which resisted all kinds of treatment. He was a temperate man, and had never had syphilis. There was a good deal of fœtor and salivation. The glands were not enlarged. After trying various methods of treatment, he gave the man a grain of opium three times a day. He rapidly improved, the pain being assuaged, and his general health better.

Case of Excision of Knee-joint by Vertical Incision.—Mr. Herbert Allingham showed two cases of central vertical excision of the knee-joint, and one of division of the ligamentum patellæ of many years standing, the result of accident. He insisted on the fact that it was possible to thoroughly explore the joint by means of this incision, which had the advantage of not weakening the action of the muscles subsequently. He had operated on six cases in that manner.

Subcutaneous Rheumatic Nodules.—Dr. A. Garrod showed a lad, æt. fourteen, with rheumatic family antecedents, and a history of having had rheumatic fever four years ago. He had loud presystolic and systolic nitral murmurs. For five months he had had rheumatic nodules in various parts of the body, especially near the elbows and the knees. The only other rheumatic manifestations observed during the present attack was stiffness of joints, rapidly yielding to treatment. The general health of the patient appeared good.

Sporadic Cretinism and Bossed Skull.—Dr. Angel Money showed a child, æt. three years, with marked signs of cretinism. The chief interest in the case was a considerable bossing of both parietal bones, giving rise to a maliform skull. The bossing might have been due to bad feeding, to syphilis, or to the same cause as the cretinism. It was possible that congenital syphilis might be an occasional cause of cretinism.

* * * *

Clinical Society of London (Christopher Heath, president). **Suppression of Urine caused by Impaction of Calculi in both Ureters relieved by Operation.**—Dr. C. H. Ralfe and Mr. R. J. Godlee furnished particulars of this case. The subject, a lady twenty-six years, had suffered from rheumatism four years previously, and also from renal colic on both sides and hæmaturic. On July 31st, 1888, she had an attack of renal colic, which passed off, and on August 8th had complete suppression of urine for fifty-three hours. The left kidney was exposed in the usual manner, and incised, very little urine escaped, and no stone was found; but on passing the finger down the course of the ureter a small stone was felt about two inches below the kidney. The ureter was drawn towards the wound, and opened by an incision sufficient to allow of withdrawal of the stone; a tube was left in the kidney. There was an immediate relief of the symptoms. Large quantities of urine were passed by the wound, but none by the urethra for three days. On August 13th there was a slight attack of right renal colic, and another on the 23rd. On the 15th, the tube and stitches were removed, and on the 28th the wound was completely healed. On September 3rd, the right kidney was incised, but only a mass of gravel was found in it, and no stone was found in the uretha, though it was traced down as far as the point where it crosses the iliac vessels. Blood appeared in the urine immediately after the operation, and also gravel. The bladder was also sounded, but no stone was struck. On the following day a small stone was passed per urethram. Between this and the end of October the patient had three attacks of colic, which were rather severe. She is now, however, perfectly well.

* * * *

Hunterian Society (R. Clement Lucas, B.Sc., F.R.C.S., president). **Peripheral Neuritis following Typhoid Fever.**—Mr. F. Rowland Humphreys showed a case in a girl, æt. three years.

She had an attack of typhoid fever in September last, with cerebral symptoms, etc. In the fourth week the abdominal reflexes were greatly increased with pain and flexion of the legs. On November 15th, she was able to sit up, but could not lift either leg or walk. To the faradic current there was no response in any of the muscles of the lower extremities. A week later the right extremities were greatly improved, but the left abdominal muscles were noticed to "belly out" with crying or movement. The reaction was similar to that of the other muscles. On December 23rd, the child was able to walk a few steps by herself, and on February 26th, all the muscles, except the left tibialis anticus and the abductors of the left thigh, and the abdominal muscles reacted to the interrupted current, and the child walked fairly well.

Hydatid of the Liver.—Mr. John Poland showed a case of cured hydatid of the liver in a boy, æt. seventeen years. The swelling had appeared for a little over five months and a half previously, and had steadily increased. Pus, with some hooklets, was withdrawn by the aspirator. Four days later, a free incision three inches and a half in length, under carbolic spray, was made through the abdominal walls and peritoneal cavity into the cyst, cutting through about an eight of an inch of sclerosed liver tissue. The cyst was freely opened, and the liver carefully stitched to the peritoneum and the abdominal wall. About five or six pints of pus were evacuated, besides hydatid membranes, and a large drainage tube introduced. Three weeks after the operation the wound was completely closed, and the patient well.

Dislocation of Feet.—Mr. W. F. Hall stated a case of sub-astragaloid dislocation of both feet, under the care of the president. The displacement occurred seventeen years ago through the man, æt. forty-five, falling into a threshing machine. The dislocation was most marked in the right foot, where besides the subastragaloid luxation, the astragalus was twisted on its rectical axis, the tread of the foot occurring on the tread of that bone which pointed forward, downwards, and inwards, and was covered with a large bursa. In both feet the arches were lost, the soles presenting a perfectly flat surface. In both feet also the toes were pointed outwards, but more markedly in the right, the whole deformity presenting an appearance like that of flat foot.

Cork Medical Society (Francis Greene, M.D., in the chair). **Exfoliation of Parietal Bone.**—Dr. Macartay read notes of a case of fracture of the skull, followed by exfoliation of the parietal bone. He exhibited two pieces involving the entire thickness of the bone.

Treatment of Genu Varum.—Dr. Grattan exhibited a little girl, whom he treated by fracture with his special clamp. The limbs were perfectly straight, and the patient could walk well.

Craniotomy.—Dr. Greene read notes of a case in which he had performed craniotomy and evisceration. Injections of antiseptics after removal of the placenta were used, and the patient made a good recovery. Several members joined in the discussion which followed.

Sudden Death after Parturition.—Dr. Burke related a case. The patient a primapara, æt. forty, had a difficult labour on November 24th, with instrumental delivery. On the fourth day the temperature rose to 102°, but subsided two days later. She progressed favourably until December 9th, when symptoms of lobar pneumonia suddenly developed at the right base; this resolved under treatment without leaving any trace. On December 18th, having eaten a good dinner, and to all appearances being perfectly healthy, she was seized suddenly with a violent pain in the cardiac region, and expired at once. A discussion as to the cause of death followed.

* * * *

Pathological Society of London (W. H. Dickinson, M.D., F.R.C.P., president). **Bronchial Carcinoma.**—The Secretary read the report of the Morbid Growths Committee on Dr. Handford's specimen of carcinoma of the left bronchus, which had been referred to them at the meeting held on February 5th, 1889. The members of the Committee stated that they agreed with the views of the author; that the specimen was a primary carcinoma of the mucous membrane of the bronchus.

Congenital Growth of the Larynx.—Mr. Lennox Browne exhibited the larynx of a child, æt. three, who had since birth been the subject of neoplasms which had blocked the glottis to such an extent as to threaten asphyxia. Intubation was attempted, but causing hæmorrhage, tracheotomy was promptly performed. Active bleedings had taken place twenty-four hours later, and death occurred forty hours after the operation. The necropsy demonstrated that the first hæmorrhage occurred from an abrasion of a growth on the right vocal cord by the intubation instrument, but that the latter ones were due to the circumstance that the lungs had never properly expanded, being no larger than those of a newly-born infant, and that the tissue had given way under the suddenly increased volume of air afforded through the tracheotomy tube. The case was interesting, as presenting a hitherto unrecorded danger of tracheotomy in cases of congenital laryngeal obstruction, and also as pointing to the risk in performing intubation in cases of laryngeal growths. Mr. Bland Sutton asked what was the nature of the growth. Mr. Lennox Browne replied that it was a true papilloma.

Syphilitic Ulceration of Trachea and Large Bronchi.—Dr. Gulliver showed and described a specimen of this nature which had been taken from the body of a woman, æt. thirty-two. The lower part of the trachea was ulcerated, also the bronchi. The ulcers were elongated in form and transverse in construction. The syphilitic lesion found was ulceration of the palate. The cause of death was broncho-pneumonia.—Dr. Penrose asked if a microscopical examination had been made?—Dr. Gulliver said none had been made, as it was not considered necessary.—Dr. Quain asked what was the condition of the bronchial glands? and referred to their enlargement being a cause of stridor.—Dr. Gulliver said in this case the stridor was due to the construction of the trachea, though the bronchial glands were enlarged secondarily to the ulceration.

* * * *

Royal Academy of Medicine, Ireland. *Section of Obstetrics.* Friday, February 1st, 1889 (W. J. Smyly, M.D., F.K.Q.C.P., president). **Amputation of Cervix Uteri in Treatment of Uterine Cancer and Cervical Injuries.**—Dr. More Madden read a communication on the above subject. He described from the standpoint of his own clinical experience, as well as from the literature of the subject, the expediency of the timely removal of the cervix uteri in cases of threatened or early existing malignant disease. Moreover, he further urges the utility of this operation as a substitute for cervical tracheloraphy in some cases of laceration and its consequences. Cancer of the uterus is not only the most formidable, but is also unfortunately amongst the most frequent of all the special diseases to which women are subject, and in the great majority of cases he believes it originates as a local disease in the cervix, in which, if there recognised in time, and treated by immediate intra-vaginal amputation of the cervix, it may possibly be arrested. Secondly, if not thus checked, the subsequent extirpation of the entire uterus, as now advocated by some authorities, is an operation which, if not worse than useless, can seldom be resorted to with any great probability of ultimate success. And thirdly, that in cases in which, as will be shown, there is a likelihood of cancer becoming subsequently developed in cicatricial tissue resulting from extensive parturient lacerations not reparable by tracheloraphy, the cervix should be unhesitatingly removed as the only effectual preventive measure for a disease for which, when established, there exists no reliable curative treatment. Within the last twelve years a very considerable number of cases of uterine cancer, chiefly epithelioma, have come under observation in the gynæcological department of the Mater Misericordiæ Hospital, and in the great majority of these the disease primarily manifested itself in the cervix, whence, if unchecked, it gradually extended upwards into the body of the uterus.

The future of this disease will be better if we operate early. This, however, depends on our early diagnosis, and under these circumstances the diagnostic utility of the curette becomes unquestionable; and for this purpose its cautious employment, so as to bring away a sufficient amount of the abnormal tissue for microscopic examination, should immediately be resorted to in every case of suspected or possible adenomatous or cancerous degeneration.

The question of the expediency of operative interference in these cases, by removal of the cancerous cervix, must be determined on similar principles to those recognised in other forms of malignant disease. Thus, for instance, no surgeon would be justified in amputating the cervix in cases where the cancerous cachexia was well established and obvious in the general aspect of the patient, or where the disease was either developing with unusual force and rapidity, or else had extended beyond the cervical zone, as to render it impossible to thus remove completely the implicated part.

Within the past few years the writer has amputated the cervix in eighteen cases for cancer, or what appeared to him to be symptoms of incipient cancer; and all the patients thus treated recovered from the immediate effects of the operation. In four of them the disease recurred either in the uterus or elsewhere within a year; in two it returned within two years; in one instance the patient returned two and a half years subsequently, with a large cancerous ulcer of leg, from which she died shortly afterwards; and in another it recurred two years later. Ten cases have results since continued, as far as he knows, in

good health. The comparative value of extirpation of uterus having been first discussed, considering, therefore, the extreme liability to the occurrence of cancer in the vicinity of cervical lacerations, the difficulty of early recognition of the disease and the great uncertainty of treatment by any operation after the disease has become evident, Dr. More Madden would, therefore, venture to urge the removal of the cervix, not only in cases of cervical cancer, but also in all cases of extensive areolar hyperplasia consequent on parturient laceration as a preventive of the possible development of uterine cancer. This rule of practice may be objected to, as involving an unjustifiable and meddlesome surgical interposition in cases where the disease might never occur were the patient left unmutilated by the removal of the cervix uteri. But though this may possibly have been the case in some of the instances in which he performed the operation in question, it will bear that reproach with perfect equanimity as long as he is satisfied that by its adoption he has been instrumental in any single instance in warding off a disease so dire as cancer, which, as before observed, clinical experience has proved most liable to attack the cervical tissues in the cases above refefred to.

With regard to the utility of amputation as a substitute for cervical trachelorraphy in some instances, Dr. More Madden urges that in certain cases of extensive stellate laceration of long standing, with considerable loss of substance, and accompanied with chronic inflammatory conditions of the adjacent structures, or cellulitis, as well as with hypertrophy or hyperplasia of the injured cervix, caused by inflammatory exudations, trachelorraphy is inapplicable, and such cases may, he believes, be better treated by the amputation of the mutilated and diseased cervix. Moreover, this operation, according to his experience, is fully justifiable in some cases of non-traumatic hyperplasia, and chronic parenchymatous cervicitis, more especially, as already pointed out, in patients who are hereditarily predisposed to malignant disease, as well as in some instances of cancer of the cervix, either as the most certain prophylactic of uterine cancer, or else as a possible curative measure in the early period of the disease, or, if for nothing else, merely to relieve suffering, if not to prolong life in its latter stage. Finally, although in the majority of the cases of laceration in which the cervix has been removed the patients have since remained sterile, still, on the other hand, there can be no doubt that this operation is called for in some cases of sterility, resultfrom the mechanical obstacle to impregnation offered by a greatly hypertrophied, elongated, and conical cervix uteri.

Within the last few years Dr. More Madden has, for the foregoing reasons, amputated the cervix in a considerable number of instances; and so far at least he has had no experience of the many disastrous consequences that some writers insist on ascribing to this operation, but which he thinks may possibly, in some instances at least, have originated from want of familiarity with the details of the procedure by which it may be best accomplished, as well as from its employment in unsuitable cases.

* * * *

Yorkshire Association of Sanitary Inspectors.—On March 16th, the quarterly meeting of the Yorkshire Association of Sanitary Inspectors was held in the Town Hall, Halifax. There was a large attendance, including representatives from the following places :—Leeds, Bradford, Halifax, York, Goole, Sowerby Bridge, Elland, Holmfirth, Tadcaster, Keighley, Barnsley, Bingley, New Mills, Batley, Huddersfield, Hebden Bridge, Netherton, Altofts, Ovenden, South Crosland, Ilkley, Kirkheaton, Rothwell, Thornton, Heckmondwike, Dewsbury, Cleckheaton, and Wetherby. Several members of the Halifax Corporation were present, including Alderman Pollard, Mr. J. Mann, Mr. I. F. Coe, and Mr. J. Wadsworth, members of the Sanitary Committee. Prior to the meeting the gentlemen visited the Corporation sanitary works at Stoney Royd.

Mr. T. Pridgin Teale the president, was announced to preside, and until his arrival Dr. T. M. Dolan was voted to the chair.

In opening the proceedings, Dr. Dolan pointed out that the members of the association were, as it were, sanitary missioners, going about the country to preach sanitation. By the strict carrying out of sanitary measures the appalling mortality of the country might be much reduced. He had pleasure in bearing testimony to the good work done by the sanitary authorities at Halifax, and to the interest taken in sanitation by the members of the Sanitary Committee. In Halifax they were fortunate in the possession of a good water supply, and it was pleasing to note the regulations that were carried out as to cleansing the streets, &c.

Mr. Teale, who arrived shortly after the conclusion of Dr. Dolan's remarks, then took the chair.

Dr. G. Goldie (medical officer of health, Leeds) read a paper entitled "The Necessity for Public Notification of Infectious Disease, and the Difficulties," in the course of which he said his experience of sixteen years had convinced him that sanitary inspectors were as much interested in that subject as medical officers of health. They were advocating legislation to enforce the public notification of infectious diseases. Small-pox, he proceeded, was especially dangerous and contagious, and in order to prevent its spread, it was very necessary to isolate and notify the case. Typhus, although very liable to spread, could be much more easily dealt whith. He had frequently been called in to disinfect a house in which an infectious disease raged, where he felt he was "locking the stable door when the horse was gone." He urged that there was no more interference with the liberty of the subject in compelling the notification of disease than there was in the compulsory registration of births, marriages, and deaths, and also vaccination. A second form of objection to notification was that the patients would be sent to the hospital, but he pointed out that compulsory notification would not in that respect alter in any way the requirements of the Public Health Act, 1875. The medical attendent must necessarily be the first to notifiy the disease. He must tell the person in charge of the patient of the disease such patient was suffering from; and why should he not notify straight to the sanitary authorities?

In the discussion which followed Mr. Atkinson (York) said they had compulsory notification in that city, and it had worked satisfactorily.—Mr. Sykes (Holmfirth) urged that they should endeavour to attain their object with as little friction as possible. All law was in a sense compulsory. Hence there was nothing very objectionable in that, but they wanted to look at the matter all round, and devise the best means by which their object could be attained.—The Chairman expressed the opinion that the country must come to it sooner or latter. Its establishment was the natural outcome of sanitary work. Why should not the fact of illness be communicated to the authorities at its beginning, as they must necessarily communicate it at the end? The fact that public notification was already in force in some forty towns in the kingdom, and that it was working satisfactorily, showed that it must come to be a national thing. When the time came for its adoption, there would not, he believed, be the opposition to it on the part of the medical profession which would have been the case some four years ago.

In his reply on the discussion, Dr. Goldie expressed the opinion that local notification was of very little use. He asked distinctly for an Imperial public Act. He saw no medical difficulty in the matter at all. An Imperial Act rendering notification compulsory would also have the effect of compelling urban rural authorities to provide hospitals to which cases could be removed.

Mr. J. E. Coe (a member of the Halifax Town Council) moved a vote of thanks to Dr. Goldie for his paper. This was seconded by Alderman Pollard, and was cordially given.

Dr. Solomon C. Smith (Halifax) read a paper on the subject of "Syphonage as a cause of ineffectual trapping." Syphonage was the vice which traps possessed of sucking up the water, without which a trap was useless. One of the causes of syphonage was capillary attraction, and was a very fertile cause indeed. One method of preventing this form of syphonage was by putting a good grating at the top, so as to prevent hairs and such things from getting into the trap. Another preventive was by having the interior of the trap as smooth as possible. The pressure of the atmosphere was another cause of syphonage, and Dr. Smith proceeded to illustrate this in an interesting manner. Suction by the water falling down from the pipes, friction of the water passing the junctions in the pipes and the air friction caused by freely-flowing water down a soil pipe were the main causes of syphonage, but he wished to point out that none of these causes would of themselves empty the trap, because the drain side of the trap would always be left full. The remedies he recommended, so far as traps were concerned, were a quick bend; deep, straight up-and-down traps, which work the best, and the up-cast shafts, widened as much as possible. But no trap would resist soap and gummy materials. They must find something to resist syphonage outside the trap itself, and that was by a ventilation pipe. The only thing that could, in his opinion, radically cure this vice of syphonage was by having ventilation from the top of the trap, and it would pay eventually by the increased durability of the trap through its being protected from the corrosive action of foul air.

A cordial vote of thanks was accorded to Dr. Smith for his paper.

* * * *

British Gynæcological Society, March 13th, 1889 (Dr. Dolan, Vice-president, in the chair).—The President said that in the absence of Dr. Macan, he would, on taking the chair, express his sense of the honour done him in electing him a vice-president of this important and prosperous Society, but he took it that it was meant as an expression of

recognition of the large class he represented, and as another instance of the cosmopolitan spirit of the Society which did not confine its honours to one class, or to one locality.

The Secretary read the report of the last meeting of the Council, at which the following resolution was passed :—

"In the opinion of the Council it is highly detrimental to the interests of the British Gynæcological Society that its Fellows should advertise their medical works, or allow them to be advertised, in the lay press."

The resolution was moved by Mr. Lawson Tait, seconded by Dr. Bantock, and adopted unanimously.

Mr. Tait congratulated the Society upon having obtained the adhesion of the Professor of Midwifery of the University of Edinburgh as a Fellow of the Society.

Fibroid Tumour of the Uterus.—Dr. Bantock then showed a specimen which he said raised the question of the removal of fibroid tumours of the uterus. The question had been raised as to the class of cases most suitable for removal of the appendages and those best dwelt with by hysterectomy. The case in point was one for the removal of the tumour. It was one of those soft fibroids which attained such enormous dimensions. They were very rapidly in growth, and in that case the existence of the tumour had only been noticed a few months before. It was situated in the right broad ligament, and was adherent to the right side of the uterus, as shown by the red surface in the specimen. It was shelled out of the broad liagment with readiness until he got down to the pedicle, when he had to apply a ligature. The patient recovered without a bad symptom. She was a single woman, æt. forty. He had operated on the 4th of the month, and she was now quite convalescent. The tumour weighed three pounds three ounces.

Case of Twisted Pedicle.—The second specimen illustrated another subject of recent discussion. It was a case of twisted pedicle of a dermoid cyst. The Fallopian tube which was seen on the surface was in an œdematous condition. It illustrated the remarks he had made some time ago, when Dr. R. T. Smith brought forward a case of twisted pedicle. The patient had been brought to him about three weeks ago in a very distressing condition. She had been seized a week before with sickness, acccompanied with severe abdominal pain and extreme shock. He discovered a tumour on the lower part of the abdomen, more particularly on the right side. He at once ventured on the diagnosis, that the symptoms were due to the twisting of the pedicle of an ovarian tumour. They had only been able to operate on her on that day. He recalled that when the matter was under discussion he had expressed the opinion that it was not desirable to operate upon the patient while suffering from the immediate symptoms of twisting of the pedicle, and particularly to the accident that usually accompanied twisting of the pedicle—viz., hæmorrhage into the sac, which appeared to have more to do with it in the production of the shock than the twisting itself. In this patient the pedicle was twisted about one and a half turns ; it was not absolutely strangulated, but it was pretty nearly complete, and there had been hæmorrhage in the small cavity at the time of the accident. He thought that Dr. Smith's case supported this contention that it was unwise to operate during the continuance of the shock, and he could point to another case in the same condition and with the same result. He thought it was best to allow such patients to remain quiet for some time, in order that the acute symptoms might subside. A tumour, if completely strangulated, would contract adhesions to surrounding structures, and its death would thus be prevented. His conclusions had been the result of his invariable experience. He had never seen a patient die from a twisted pedicle, nor from hæmorrhage into the interior of the sac, nor had he ever heard of such a case.

The President asked Dr. Bantock whether he had understood him to say that there was shock with or without hæmorrhage ?

Dr. Bantock, in reply, said he was quite sure in his own mind whether the shock was contributed to by the twisting of the pedicle, or not the tension induced by the hæmorrhage had a good deal to do with it.

Mr. Lawson Tait said he could give a melancholy example of the results of leaving uterine fibroids alone. A lady, æt. sixty, was sent to him from Nottingham with an enormous soft œdematous myoma. Twelve years before she had been to consult Sir Spencer Wells, who for some reason advised that nothing should be done. The patient went on bleeding continuously, her menstruation practically never ceasing. The tumour went on increasing in size, and when she came to him on the 10th of December last it was of an enormous size. He advised immediate operation—warning, however, the patient that in her exhausted condition recovery was materially interfered with. She nevertheless eagerly requested the operation, as did her husband. He therefore operated, shelling it out as easily as possible, but the shock was so great that the patient never rallied from the operation, and she died about thirty-six hours after. He asserted that if the patient had been operated upon twelve years earlier, when she was fifty instead of sixty, and with ten years less of suffering and hæmorrhage, her chances of recovery would have been materially increased. As to the other points, he and Dr. Bantock were not so much agreed. He had seen thirty or forty cases of twisted pedicles or parovarian tumours, and he was strongly of opinion that it was the twisting *per se* that caused the shock. He had seen the severest shock without a drop of hæmorrhage. The balance of evidence was in favour of twisting as the cause of the shock. His rule was to operate as soon as he could get to the patient, and he had not lost a single patient. The only case of twisted pedicle under his care which proved false was one in which he did not operate, rather, he had operated in a very bad way. He must plead his youth and want of experience as an excuse; but the fact was that having found a lump in the patient's groin, she being collapsed and vomiting, he regarded it as a case of femoral or inguinal hernia, and operated for that, as he then thought, successfully. At the *post-mortem* it turned out that it was not a hernia at all, but a small hammer-headed tumour of two cysts, which had twisted and become hæmorrhagic, and the patient died from shock. It was not the amount of the hæmorrhage in that case that had determined the shock, for she could have lost two or three times the amount of blood without hurt.

Dr. R. T. Smith asked Dr. Bantock how long he had operated after he found the patient suffering from shock ? Also, had the mischief any relation to the catamenial period ? He mentioned that in both his own cases the twisting occurred when the patient was unwell, and in the course of a few day from the symptoms the shock began to pass off. In both his cases, too, the tumours were very large, one reaching fully three inches above the umbilicus. He asked whether there were any old adhesions in that case. In his first case the patient had been tapped some months before, and the folds of the tumour were agglutinated. He thought that in contracting they might have had something to do with the twisting. Their pathologist thought that this might have been the case. He thought it was important to get facts together bearing on this point. In the case that died, of course they must remember that she had pronounced granular degeneration of the kidneys. They found afterwards that the patient was accustomed to drink. In neither case did he operate for three days after the symptoms, and in the last case the patient had rallied very materially; in fact, she was so much better that he had thought it as well to postpone the operation until the following morning.

Dr. Edis, in relation to the first specimen, said that the fibroids were very rapid in growth, and sometimes obscure. He pointed out that amenorrhœa could not be relied upon to distinguish between fibroid and other tumours. He observed that all men were not ovariotomists : what they wanted was a first help in time of need—to know what were the points they ought to take up, and how to distinguish between fibroid and any other tumour; also to distinguish between those that might be operated on, and those that were best left alone.

The President said the diagnosis was always difficult with all classes, as well as the general practitioner. He related a case, with the facts of which he was familiar, as a set-off to the remarks of Dr. Edis. A very eminent surgeon came down to the country to give his opinion in respect of a case; and after a careful examination, he decided to operate next morning, but in the night the patient (a married woman) was delivered of a baby.

Dr. Macnaughton Jones said it would be a very difficult thing to draw a sharp line of demarcation, as suggested by Dr. Edis. He said that practitioners were at great pains to arrive at a correct diagnosis, and before concentrating their attention on endeavours to prevent his making mistakes, they might do well to look nearer home.

Dr. Rutherford said that in many cases, when the pedicle was tied in ovariotomy, etc., the patient had shown signs of collapse. He thought that fact bore out the views of Mr. Tait.

Dr. Bantock, in reply, said that three weeks had elapsed between the advent of the symptoms of shock and the operation. There was no connection between the occurrence of the twist and menstruation, nor could he remember any such connection as having existed in any of the many cases which he had been enabled to observe.

Dr. Routh showed an instrument which he had designed to enable surgeons to apply the wire of the écraseur or galvano-cautery high up, and to maintain the pressure. It was a very ingenious piece of mechanism, and met with the approval of the members present.

Dr. Macnaughton Jones read a paper on the "Use and Abuse of Massage," published at page 213.

On the motion of Dr. Barnes, seconded by Dr. Bantock, the discussion of this important paper was adjourned until the next meeting, Wednesday, March 29th.

Gynæcological Society of Chicago.—At a meeting of this Society, Dr. Henry Byford presented for Dr. W. Byford the following specimens: **Fatty Tumour of the Suprarenal Capsule.**—The specimen I now wish to describe, he said, is a supposed fatty tumour of the supra-renal capsule, but it was unfortunately allowed to spoil and cannot be exhibited. Mrs. Silva Walker, Pataha, W. T.; æt. thirty-eight; American. Married twenty years; has had five children, eldest nineteen, youngest ten. No miscarriages. One year and a half ago first noticed increase in size of abdomen in right side and through pelvis. Slight backache. Size increased very rapidly the last six months. Menstruation regular and normal. She was operated on November 25th, 1888, and is getting well. This, I believe, is the only fatty tumour of the suprarenal capsule which I can find on record that has been removed before death. A few have been discovered at autopsies. It weighed twenty pounds. As it filled the abdomen so completely, even pressing down the uterus, its place of origin was not determined before the operation. A future of importance in the case was the manner in which the growth was removed. It was enucleated from the capsule, and the capsule sewed with catgut and trimmed so as to make a canal from the bed of the tumour up to the external abdominal walls. The edges of this canal or sac were sewed into the abdominal wound so as to shut off the abdominal cavity; the bed of the tumour was thus treated extra-peritoneally. The kidney was removed. Whether it might have been safely left or not is a debatable question; the chances were it would have undergone inflammatory changes. Its vessels were ligatured, and the ligatures left in the capsule. A large exposed vein, at the bottom of the cavity, was clamped with hæmostatic forceps, and a large bleeding surface, on the under aspect of the diaphragm about the normal attachment of the supra-renal capsule, was gathered together in the blades of two long hœmostatic forceps. The forceps were taken off at the end of thirty hours. The patient has done very well since. The tissues, which were caught in the bite of the forceps, have sloughed out, and the cavity is healing. The other kidney secretes twenty to forty ounces of normal urine a day.

Dr. Parkes: How did you come to settle definitely that this tumour grew from the supra-renal capsule—why not from the post-peritoneal fat for a basis?

Dr. Byford: The supra-renal capsule was not found, but this tumour was attached to the under surface of the diaphragm where the supra-renal usually is. The tumour now developed above and over the anterior surface of the kidney, and did not lift the kidney forward, but rather held it back in place. There was no indication of unusual fatty development in any of the tissues about. The firmness of the capsule and its relations after enucleation favoured my view. A post-peritoneal fatty tumour about the kidney would have more lateral attachment, and, I think, develop more down the side into the iliac fossa; whereas this one, which was freely movable, pressed down in the centre of the pelvis so as to give the impression at first that it was attached to the uterus. All these facts have led me to consider the supra-renal capsule as the starting point.

Cysto-Fibromyoma of the Uterus.—The last specimen I have to show is a fibro-cystic tumour of the uterus weighing 30lbs. It was surrounded by 45 pints of ascitic fluid, so that the patient was relieved of 75lbs. of weight by the operation. What was left of her weighed about 90lbs. On the right side it has undergone myxomatous degeneration. A peculiarity is that the uterine cavity is completely obliterated half an inch below the normal-sized fundus by the tumour, and begins again lower down. The patient was about forty-four years of age and menstruated scantily. The tumour, which is known to have been growing over fifteen years, started below the fundus in the posterior uterine wall. The broad ligaments were ligated seperately, and the uterine stump treated extraperitoneally. This is the sixth day since the operation. There has been but little reaction, the drainage tube is about dry, the patient is hungry, and has commenced to direct the household affairs. Flatus passed freely from the beginning. Formerly, when I was an adherent of the intra-peritoneal method of treating the the stump, I stood in great awe of abdominal hysterectomy for fibroids, but since adopting the extraperitoneal method I find that the mortality is but little greater than after ovariotomy.

I would like to say that I have been found fault with for failing to bring microscopic slides of my specimens, or reports of pathologists upon three cases of alveolar sarcoma of the uterus, reported at the September meeting of this Society, and that my diagnosis was called in question. In my anxiety to take up as little of your valuable time as possible, I suppose that I must have omitted to state that, in the two cases shown, specimens were obtained by curettement a week before I removed the uteri, and were examined by pathologists—that from Mrs. M. by Dr. L. L. McArthur, that from Mrs. Sh. by Dr. W. J. Mergler. In the case referred to, in which the uterus went to pieces during removal, Dr. Doering, who was the family physician, had the specimen examined by a pathologist. The fourth case I casually mentioned was diagnosed by Dr. McArthur from specimens I obtained by curettement. In the case of sarcoma of the ovary, Dr. Bayard Holmes was my authority.

The President (Dr. Parkes): I have had under my control lately a large tumour of the abdomen. I decided that it was behind the intestine, because there was one channel passing over the surface of the tumour, in which one could get a gurgling sound and something that resembled the displacement of gas. That indicated that the intestine was in front, and so it proved. It was a pancreatic cyst.

Dr. W. W. Jaggard: The Society is to be congratulated upon the presentation of so much valuable pathological material at this particular meeting. I have been specially interested in the case of alleged ovarian pregnancy. Without for one moment questioning the accuracy of Dr. William H. Byford's diagnosis, I beg to remind the Fellows that cases of ovarian pregnancy are very rare. Werth has demonstrated the tubal origin of many of the cases recorded as ovarian. As an essential criterion of ovarian pregnancy, the possibility of the participation of the corresponding tube in the sac must be excluded. In the specimen, as it has been presented to-night, it is impossible to exclude the participation of the tube in the sac.

The President: I remember seeing a few years ago, in the office of Dr. Murphy, of St. Paul, a specimen of uterus and both ovaries removed after death. In one ovary there was a fœtus. The Fallopian tube and all were present.

IRISH MEDICAL SCHOOLS AND GRADUATES' ASSOCIATION.

Twelfth Annual Meeting.—Annual Report.—Statement by Sir Thomas Crawford.—Recognition of the Higher Diplomas of the Irish Colleges by the Army Medical Department.—Anniversary Dinner.

St. Patrick's Day falling this year on a Sunday, the twelfth annual meeting of the above association was held on Saturday, March 16th, at 11, Chandos-street, Cavendish-square. Among the members present were Professor Alex. Macalister, F.R.S. (President); Dr. Richard Fegan (President-elect); Sir Thomas Crawford, K.C.B., and Dr. Macnaughton Jones (Ex-Presidents); Director-General Dick, C.B., R.N.; Professor Sibthorpe, I.M.S.; Deputy Inspector-General F. W. Davis, R.N.; Drs. W. H. White, Phillips (Reading), G. Stoker, O'Brien Williams, R.N., Mapother, and the two Honorary Secretaries, Drs. Stewart and Abraham. The outgoing President having resigned the chair to Dr. Fegan (Blackheath), the latter proposed a vote of thanks, seconded by Sir Thomas Crawford, to Professor Macalister for his services during the previous year, the Chairman stating that the large-hearted hospitality shown by his predecessor on the occasion of their gathering at Cambridge last June merited a warm recognition. Dr. Robert McDonnell, F.R.S., was appointed President-elect. Dr. W. H. White was appointed Honorary Treasurer, *vice* Brigade-Surgeon W. Alexander, M.D., resigned, the latter being now stationed in Scotland. Dr. Cullimore and Deputy Inspector-General F. W. Davis, R.N., were appointed Honorary Auditors. A ballot having been taken for the fifteen members to serve during the coming year as non-official members of the council, the following were declared duly elected—namely, Drs. W. H. Bourke, Sir Thomas Crawford, Davison (Bournemouth), Director-General Dick, R.N., Gaven, Heath (St. Leonard's), W. B. Johnson, Douglas Lithgow, Macalister (Cambridge), Mapother, Phillips (Reading), Gilbart Smith, Waters (Chester), Charles Wells, and Gerald F. Yeo.

The annual report stated that the Association continued to increase in numbers, notwithstanding losses by deaths, resignations, and lapsed memberships. One foundation member (Dr. W. H. Evans, of Bradford, Yorks.), and two other members, Drs. Charles Davidson and Walton Dwyer, had died during the year. The total number now on the roll was 555, as against 517 on St. Patrick's Day, 1888. The usefulness of the Association in guarding the interests of Irish diplomates practising in England was shown by proceedings early in the year at the Bristol Royal Infirmary. A proposal was made at that institution—similar to one adopted the previous year at Liverpool—that future appointments (both medical and surgical) on the honorary staff should be restricted to those holding certain London diplomas. This attempt to increase the number of English public hospitals in which certain London Colleges have a monopoly of appointments was frustrated through the action of the Association in promptly enlightening local public opinion on the true merits of the question. The request

of the R.C.S.I., that inspectors should be sent to report on its Fellowship examination, had been refused by the General Medical Council, such inspection not being considered within their legal powers. "This official pronouncement being now on record," the report goes on to say, "good grounds exist for asking Parliament to grant the General Medical Council requisite additional powers." The Association had the matter of exclusion of Irish diplomates from hospital appointments brought under the notice of the General Medical Council at a subsequent session; but it was shelved by the "previous question" being moved and carried. The report concludes as follows: "With these facts before it, your Council can only recommend the adoption, in the immediate future, of a policy of watchfulness, so that in the event of restrictions being proposed elsewhere similar to those suggested last year at Bristol, active steps may be taken forthwith to prevent an injustice being done to the Irish diplomates in the locality, their qualifications being inferentially depreciated by such action." The report was adopted, as also the statement of the Hon. Treasurer, which showed a balance in favour of the Association of £131 2s. 5d. The latter was independent of a small balance to the credit of the "Special Fund" for disseminating literature bearing on the "hospital monopoly" question.

Dr. Mapother moved a resolution approving of the "policy of watchfulness" foreshadowed by the Council. He said he had been requested by the Royal College of Surgeons of Ireland to note the action of the General Medical Council when the question of the exclusion of their diplomates was brought up during the late session of that body. He regretted to find that the members of that august body (whom the profession looked upon as the *patres conscripti*) had not the courage to meet the difficulty boldly, but got out of the expression of an opinion by voting—with a few exceptions—the "previous question."

Sir Thomas Crawford, in seconding the resolution, said that it would be a great matter if the Irish colleges could dissociate themselves in this matter from the Scotch. He was glad to be able to announce that, as far as the Army Medical Department was concerned, a difference was to be made henceforth between such colleges as the Irish, which never admitted anyone to their higher diplomas without examination, and those (of which, in Scotland, he was sorry to say, there were one or two still) which granted similar diplomas only by election in some cases. According to a recent regulation, the value of these diplomas as proofs of fitness for promotion in the Army Medical Service is now measured by the character of the examination candidates are required to pass. As an Irishman, he was glad to say that the tests of the Irish colleges had been found quite up to the standard; and it would be, in his mind, a good thing for that Association to remonstrate with those Scotch colleges whose tardiness to adopt examinational tests for all candidates for higher diplomas was such a hindrance to them in getting the disabilities removed under which Irish diplomates resident in England were labouring at the present time.

Dr. George Stoker having stated, as an encouragement to the Council, that one of the London hospitals had rescinded the exclusive rule, the resolution was unanimously adopted.

It was announced that the summer provincial dinner would take place at Manchester this year at the latter end of June.

Votes of thanks having been passed (1) to the *Conversazione* and Dinner Committees, (2) to the medical journals for devoting so large an amount of their valuable space to reports of the proceedings, etc., of the Association, and (3) to the directors of the General Apothecaries' Company for granting the use of their board-room for the Association meetings before the Medical Society accepted them as tenants, the meeting separated.

The anniversary dinner took place the same evening at the Holborn Restaurant. Covers were laid for ninety-three, including Dr. Richard Quain, F.R.S.; Mr. Robert Anderson, LL.D., T.C.D.; and Messrs. George Augustus Sala and Harry Furniss (guests of the Association), as well as an unusually large number of ladies. The usual loyal toasts were duly honoured. The toasts of "Our Guests" was proposed by Professor Macalister (Mr. Harry Furniss responding); that of the "Army and Navy" by Dr. Quain (Vice-Admiral Curme and Major-General Philips responding); that of "Success to the Association" by Mr. Sala, who alluded to the honourable and gratifying record of the last eleven years which they could show of united action by men holding the most opposite views as to politics and creeds, having been achieved without even a whisper of discord during all that time—a remarkable testimony to the power of the medical bond. The health of the "Officers of the Association" was proposed by Dr. Robert Barnes, and responded to by Dr. Macnaughton Jones, who alluded to the fact that the numbers had more than quadrupled during the last four years.

The proceedings were interspersed with Irish songs, rendered by Miss Theresa Aungier and Messrs. Reginald Groome, W. B. Martin, and Joseph O'Shaughnessy.

Medical Miscellanea.

The subject of our next illustration will be Sir William Moore, K.C.I.E.

* * * *

The recent Russian congress was attended by 1,648 practitioners, of whom 162 were women. Of the latter, 105 belonged to St. Petersburg.

* * * *

The Duke of Buccleuch has placed the name of Sir James Crichton Browne, M.D., LL.D., F.R.S., on the Commission of the Peace for that county.

* * * *

The honorary degree of M.D. has been conferred on Dr. Hime, of Bradford, by the University of Dublin, Trinity College.

* * * *

M. Pasteur has been created a Baron, with the Order of the Iron Crown, by the Emperor of Austria, for distinguished services.

* * * *

The Queen has conferred the honour of K.C.B. upon Edwin Chadwick, C.B. Mr. Chadwick has received this favour in recognition of his invaluable labours in the promotion of sanitary reform.

* * * *

M. Berthelot has been elected by forty-seven votes out of fifty-three perpetual secretary of the French Academie des Sciences, in place of M. Pasteur.

* * * *

H.R.H. Prince Albert Victor will preside at a Festival Dinner at the Hotel Metropôle on May 29th, in aid of the funds of the Great Northern Hospital.

* * * *

The conjoint examinations of the Dublin Colleges of Physicians and Surgeons will commence on April 1st, and those of the College of Surgeons and Apothecaries' Hall on the 29th of the same month.

* * * *

The cause of sanitary reform has recently been brought prominently forward in Stockport, where it is proposed to establish a Voluntary Sanitary Associalion for the Borough, the object of the Association being to aid and support the authority of the Sanitary Committee.

* * * *

The subject of the Croonian Lecture, to be delivered before the Royal Society during the present year, will be: "Preventive Inoculation." The lecture will be delivered by M. Roux, and will be founded on observations made at the Pasteur Institute. It is hoped M. Pasteur will be present.

* * * *

Professor Gerhardt, Rector of the University of Berlin, having come to London for a consultation on March 19th, Sir Andrew Clark took advantage of the opportunity to invite a large number of professional friends to meet him. About three or four hundred attended the reception, to do honour to their German *confrère*.

* * * *

Mr. George Field, late Dean of St. Mary's Hospital Medical School, was on the 12th of March presented with a very handsome testimonial, consisting of a chimney hall clock, a very chaste tea and coffee service, and a valuable diamond pendant for Mrs. Field. Mr. Broadbent presented the testimonial, and Mr. Field made an appropriate reply amidst deafening and prolonged cheers.

* * * *

On March 21st, Mr. Henry Smith, F.R.C.S., of Kings' College Hospital, was presented with a silver salver, a complete dinner service of silver plate, and an illuminated address. A large number of past and present students—including Surgeon-General Cockburn, Messrs. Teale, Clarke, Wakeley, Fox, Rose, Barron, Drs. Duffin, Macdonald, Curnow, Pritchard, and others—assembled, and Mr. Napper, of Cranley, made the presentation on behalf the Committee in an amusing speech. The following is the inscription on the salver:—"This salver, together with other articles of silver plate, was presented to Henry Smith, F.R.C.S., by his former house surgeons, pupils, and friends, as a mark of esteem and affection, on the occasion of his retirement from the chair of Surgery at Kings' College, and the post of Surgeon to the Hospital, March, 1889."

Sir William Roberts was entertained at dinner by a large number of medical friends on March 13th. Dr. Renaud presided. Professor Morgan and Dr. Cullingworth spoke in glowing terms of the scientific advancement of the guest of the evening, also wishing him every success in his new home in London. About 100 medical men were present. During the evening an address expressing the high appreciation entertained of the services of Sir William Roberts to medical science, and to the profession in Manchester, was numerously signed. After it has been engrossed on vellum, it will be formerly presented to him.

Dr. Tatham has been appointed Medical Officer of Health for Manchester. There were forty-seven applications. Dr. Tatham's experience in Salford has eminently fitted him for the larger sphere of duty in Manchester. Dr. Tatham's first appearance was as House Surgeon to the Ancoats Dispensary. He afterwards held the post of Resident Medical Officer to the Salford Poor-law Union. Dr. Tatham was one of the first to recommend a special course of study for intending candidates for the Public Health Medical Service. He received from the Dublin University, a few years ago, the honorary degree of M.D.

We have pleasure in directing attention to the merits of what is termed the "British Stylographic Pen," which we are now using, and which we find possesses many advantages over pens of this construction. It is well made, and consequently durable. It is light in the hand, and being simple of construction, it cannot easily get out of order. Many of these pens are very high priced, and some of them are very disappointing, owing to leakage, etc. The British stylographic pen is manufactured at a price to place it within the reach of all.

The following prizes are offered by the *Société de Psychologigue*, of Paris, in 1890. The Anbance prize, of 2,400 francs (£96), for the best essay on the difficulties of differential diagnosis of general paralyses, with the various forms of insanity; the Belhommne prize of 1,000 francs (£40), for the best essay on the mental condition and delirium in idiots and imbeciles; the Esquirol prize of 200 francs (£8), with the works of Esquirol, for the best manuscript essay on some point of mental pathology. Essays, whether printed or manuscript, must be sent before December 31st, 1889, to the secretary of the society, M. Ant. Ritti, Medecin de la Maison Nationale de Charenton.

* * * *

The first triennial prize of two hundred and fifty dollars, under the deed of trust of Mrs. Wm. F. Jenks, has been awarded by the Prize Committee of the College of Physicians of Philadelphia, to John Strahan, M.D., M.Ch., M.A.O. (Royal University, Ireland), 247, North Queen-street, Belfast, Ireland, for the best essay on "The Diagnosis and Treatment of Extrauterine Pregnancy." The writers of the unsuccessful essays can have them returned to any address they may name, by sending it and the motto, which distinguished the essay, to the chairman of the Prize Committee, Elwood Wilson, M.D., College of Physicians, Philidelphia. The trustees have made arrangements with Messrs P. Blakiston, Son and Co., 1012, Walnut-street, Philadelphia, for the publication of the successful essay, which will also appear in the transactions of the College for 1890.

* * * *

The following is the quotation for which one of our correspondents asks. It is taken from Jowett's work on "Canine Madness." "It is painful to speak of one's self, but I may perhaps here be permitted to say that I have been bitten four times by dogs decidedly rabid. At each time I freely applied the caustic to the wound. I am living to the present day. I have operated on more than four hundred persons, all bitten by dogs, respecting the nature of whose disease there could be no question. I have not lost a patient. I am bound to add that one of the surgeons of St. George's Hospital told me that since his connection with that establishment he and his colleagues had operated on more than as many thousands bitten by dogs (he could not say that all of them were rabid), and he was not aware that one of them had been lost."

The *Journal de Médicine de Paris* tells us that in the Department of the Seine there have been nineteen deaths from rabies since 1888, though the mean mortality in former years never exceeded six. Rabies is on the increase in France; whilst at the same time terror drives the ignorant to Paris. The following story is but too true: In the *Petit Journal*, March 19th, 1889, it is recorded that two persons died at Jarville of hydrophobia. A regular panic ensued, and out of a town of 1775 inhabitants, about forty went to Paris to the Institute for inoculation. The facts as gathered from a medical man at Jarville are as follows: "There has been no case of hydrophobia at Jarville; but Dame Boulin had a dog. Becoming ill she gave the dog away. On the 10th of March Dame Boulin died, after hæmorrhage, caused by cancer of the stomach. The dog had many owners, and one of them died of delirium tremens. So we have here the old story of the black crows. The owners of the dog, and those who had frequented the *café* of Madame Boulin, terrified by the report about hydrophobia, have rushed up to Paris, and will in due time swell the statistics." These are the incontestable facts, and they have a ludicrous as well as a tragic side. Another death is reported—Ernest Ray, of Oissel, bitten December 13th, treated from the 17th to the 6th of January; died of hydrophobia February 25th.

Surgical Aids and Appliances.

119.—ELECTRIC PHOTOPHORE.

According to Dr. G. Beck's *Illustrirte Monatsschrift der Aerztlichen Polytechnik*, Series V, p. 202, Dr. Trouvé, of Paris, has succeeded in constructing an excellent illuminating apparatus, based on the principle of Swan's lamp, the incandescent light being generated *in vacuo*. The apparatus (fig. 1) consists of a short tube, the posterior end of which is

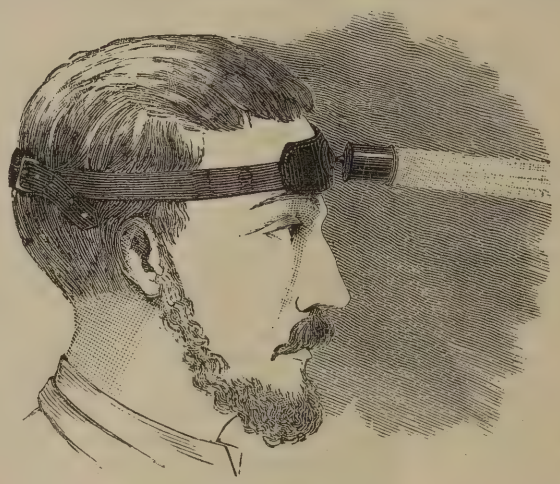

FIG. 1.

closed by a concave mirror, while in the anterior one a convex lens is placed. In the centre of the tube a Swan's glass globe is fixed, which is brought into communication with a bichromate of potash battery, by means of conducting wires entering the tube through its upper walls. The light thrown by the photophore is very intense, and remains equally brilliant for several hours after charging the cells. The lens is movable, and hence allows the illumination field to increase or decrease according to the practitioner's desire. The apparatus, furnished with a ball joint, may be fixed either on the practitioner's forehead (by means of an appropriate supporting strap), or on a metallic staff affixed to the apparatus case. The current is supplied by a large-sized battery, consisting of four zinc and carbon cells, with a solution of bichromate of potash (666 parts) in sulphuric acid (2,000) and water (5,330). The price of the photophore is 60 francs; that of the battery, 130 francs. In an editorial note, *l.c.*, p. 203, Dr. Beck adds that the apparatus works most satisfactorily, and is eminently suitable for ophthalmological purposes, provided that the light is kept within very moderate bounds, and the lamp is placed at the side of the patient. Since the bichromate battery proves to be rather expensive, Dr. Beck advises to employ Bunsen's cells, which are by far cheaper.

120.—ELECTRIC BATTERY FOR DENTISTS.

In Dr. Beck's *Revue Illustrée de Polytechnique Médicale*, November 30th, 1888, p. 353, Professor L. Serres, of the Paris Odontological School, highly recommends a bichromate of potash battery (fig. 2), constructed for odontological purposes by Dr. Trouvé. It is composed

of six cells, arranged in an ebonite box, with a travelling (up and down) board carrying the elements, which can be immersed at will into the bichromate solution by lowering, or put out of work by raising, the

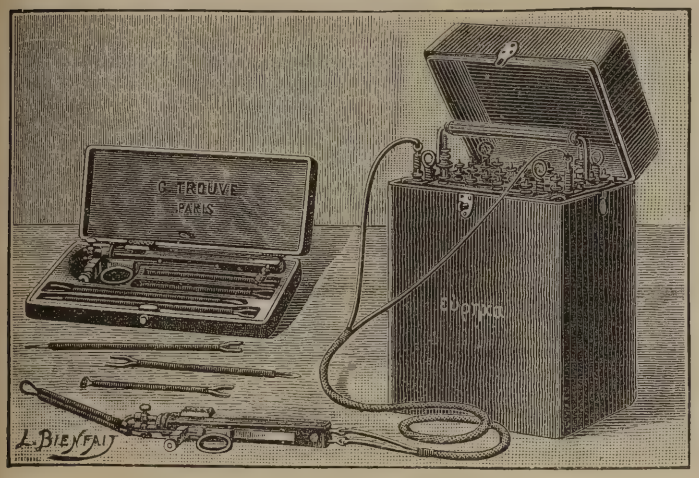

FIG. 2.

plank. The battery, fully charged, weighs about three kilogrammes; it is very portable and handy. It has an electro-motive power of 1.9 volt, and an internal resistance of from 0.09 to 0.10 ohm per cell. The price of the appliance is fifty francs; that of each fresh charge, about forty centimes.

121.—TROUVÉ'S ELECTRIC AUXANOSCOPE.

Dr. Trouve, of Paris (14, Rue Vivienne), describes (Dr. G. Beck's *Revue Illustrée de Polytechnique Médicale*, 1888, No. 3, p. 85), under the name of an "auxanoscope," an ingenious apparatus of his invention, which is destined for demonstrating (projecting on a screen) in considerably magnified dimensions (about twenty times) any opaque objects, including pictures, photos., etc., without using any transparent *clichés;* in fact, the apparatus may be justly named "a magic lantern for opaque bodies." As the editors of the *Revue* expect, the auxanoscope will prove invaluable, not only in the hands of teachers, as an excellent means for demonstrating minerals, insects (alive or dead), anatomic specimens, etc., but also in those of practitioners, as a powerful auxiliary in studying cutaneous and surgical diseases, etc. The apparatus are of two kinds, single and double. Their construction is exceedingly simple in both of the cases. A single auxanoscope (fig. 3) consists of

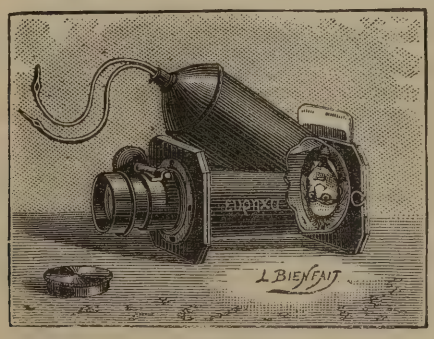

FIG. 3.

two hollow cylinders joined at a certain angle, one of which carries about its upper extremity an incandescent electric lamp, with several parabolic mirrors (for concentration of the light), while the other contains an ordinary photographic lens. The object which is to be projected on the screen is placed at the junction-angle. A double auxanoscope, which may be used for projecting both opaque and transparent objects, differs from the single one mainly in its being furnished with two cylinders containing the lamps. The battery employed for the apparatus is very portable. It has an electro-motive force of 1.9 volts, and an internal resistance of from 0.09 to 0.10 ohm per cell. Each fresh charge (sufficient for a three hours' work) costs only twenty-five centimes. The price of the apparatus (without the battery) is from 50 to 60 francs.

Correspondence, Notes, and Queries.

Communications, Books, etc., should be addressed directly to the Editor, "*The Provincial Medical Journal*," *Horton House, Halifax.*

Matters of business should be addressed to the Publisher, at the Offices, 10, *Friar Lane, Leicester.*

We cannot undertake to return rejected MSS. unless stamps sufficient for their postage are enclosed.

We shall be glad to receive reports of Medical Vacancies, Appointments, Meetings of Societies, etc.

Papers containing passages for consideration should be marked.

Correspondents must please attest their communications with their proper name and address (not necessarily for publication).

Contributions must be written on one side only of the paper.

MSS. intended for publication to be sent in not later than the 16*th of the month.*

The insertion of any letter in these columns cannot be taken as necessarily indicating our adhesion to the views or statements therein expressed. The same remark applies to articles to which a name or nom-de-plume is attached.

THE TREATMENT OF ACUTE DISORDERS OF THE RESPIRATORY ORGANS.

To the Editor of The Provincial Medical Journal.

Sir,—The great importance of this subject must be my excuse for criticising Mr. Burman's communication in this month's issue. I read a paper in the Therapeutic Section at the Glasgow Meeting of the British Medical Association, advocating modes of treatment totally at variance with those given by Mr. Burman. I also published a letter in your columns on February 1st, 1887, advocating the use of iron in its strongest and most astringent forms in bronchitis; and I am of the same opinion now, that iron is our sheet anchor in dangerous forms of bronchitis, pneumonia, and broncho-pneumonia, when collapse tends to set in from suspended respiration, due to abundant secretion, and consequently imperfect aëration of the blood.

If Mr. Burman will give more iron and less ammonia, he will, I am confident, have less to say about "contemplating the appearance of capillary bronchitis with the gloomiest forebodings." Let him give drop doses, or even two-drop doses of the strong perchloride every quarter of an hour, in his next case of that common complaint in a child, and I am sure he will be satisfied with the result.

Bronchitis being an inflammatory affection, the treatment at the outset should be directed to procuring resolution, firstly by depressing the heart's action with ipecacuanha, and secondly by giving agents which disperse stagnating blood. If I catch a case in its initial stage, I give five minims of liq. am. acet. conc. and five of vin. ipecac. every hour or two hours. In this way an attack may very often be cut short in eight or ten hours. If, however, there be any sign of debility or asthenia, I always add drop doses of iron. Indeed, in a delicate child, with acute bronchitis, I would consider the administration of the acetate of ammonia risky, as tending to induce a defibrinated state of blood, and to increase the usual danger of capillary bronchitis supervening. I often, for this reason, give spirits of nitrous ether as the diaphoretic. Again, in croup I have had great success with nitrous ether, iron, and ipecacuanha. Thus recipe: sp. etheris nitrosi ʒii., vin ipecac. ʒiss., liq. ferri perchlor. fort ♏xv., syrupi ad ʒiss. M. One teaspoonful every half hour, hour, or two hours.

In bronchitis, the carbonate of ammonia should, I think, never be given in the acute stage, because of its great liquefying properties. The acetate is preferable because it is compatible with the perchloride of iron in the event of all liquefying remedies having to be discontinued. My prescriptions show combinations of ipecacuanha, liquor ammoniæ acetatis and iron perchloride. The only sedative I consider admissible is chloral for urgent cough, in half grain doses. Even that is best done without. If the case should become capillary, I give iron only and some stimulant. By this method I have not lost one case out of forty or fifty. In all cases of bronchitis in children, I have seen great benefit derived from the vigorous application of St. John Long's liniment to the chest, three times a day. But, as I said in the opening paragraph of this epistle, iron is our sheet anchor in dangerous cases of bronchitis, be the patient young or old.—I am, Sir, your obedient servant,

March 12th, 1889. C. R. ILLINGWORTH, M.D.

THE PROPOSED HOSPITAL TAX AND THE EVIL IT WILL WORK.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—An effort is being made to induce, but in reality compel, the wage-earning classes to pay 1d. per week or 4s. 4d. a year, to the medical charities. Hospital managers seem so enamoured with the continental plans of municipal or State support that they are striving hard to have a modification of it introduced here.

A Royal Commission is called for, but one fears that those who call for it have no intention of trying to check the gross abuses, but only mean to obtain more funds to carry them on. At present there is a breakdown of our hospital management, and a strong effort is being made to fix their support on the shoulders of the wage-earners. The old plan of annual subscriptions is dying out, for hospital committees say the amount thus obtained is less each year. Next, the Hospital Sunday Fund is not answering the great expectations of its founders. Again, the wage-earner have been appealed to, and the Hospital Saturday Fund has not turned out as well as was expected. The plan of selling drugs to patients at the charities has been tried, and with as poor a result. Lastly, the London hospital committees have hit upon he above plan. That the wage-earning classes look upon this 1d. a week payment as compulsory is evident. As it is, I know of two men who were told they might leave they employ if they did not pay 1d. each week. Some return is also expected, for at the London meeting a working man asked what he was to receive for his 4s. 4d. a year, as at present he had a club doctor for 3s. 6d. Not only will this tax allow the wage-earner to demand aid as his right, but he will have the power to refuse certain treatment, as a private patient now has. He will also demand a voice in the control of the hospital, taxation and representation going together.

I wish to further point out that if this tax is established it will put an end to our Hospital Sunday collections, for few clergymen will care to quote Scripture when appealing for money. One might as well expect income-tax and poor rate collectors to do so. It will be equally absurd to refer to hospitals so supported as the outcome of Christianity. Even now it is noticed how, when an appeal is made, the term "medical charity" is used, but that when urging wage-earners to give we invariably speak of "the hospital." It will, moreover, be natural for those who give 4s. 4d. a year, to object to be termed "charity cases."

At present the attempt to pass off our hospitals as medical charities is simply absurd. Merchants for the most part support them, because they find this is the cheapest plan of obtaining medical relief for their *employes*, knowing full well that nothing throws an office so much out of order as the absence of hands. It has been shown that this country loses about £20,000,000 each year, through sickness alone, "National health is national wealth." Wage-earners say it is the duty of their employers to provide medical aid for them, as their wages are not sufficient to allow them to pay for this themselves, and as their masters find the hospitals a good way of obtaining cheap medicine, they support it. Small trades-people say the hospital is a grand institution, because they can get a doctor and medicine for nothing, and so escape payment, while they defraud the genuine poor. Lastly, medical practitioners find they can improve their financial and social conditions by being on a hospital staff, and hence their struggles and unseemly touting to secure a place. Out of all these eminently selfish actions the present abuses have sprung and hence it is that our hospital committees will not—some say dare not—allow a genuine investigation to take place into the social circumstances of their patients.

No one wishes our medical charities to cease their good work; but would like to know why committees want to change them into financial undertakings. If they charge a certain sum, and make wage-earners pay, are they not following the plan of sick clubs? Are the latter charities? Is it not rather a parody on our present hospital management, after they had done all in their power to smash up the provident dispensary movement, to find them now trying to follow out the rules of the latter by making people pay to a charity when well, so that they may obtain treatment while ill. Let our workhouse infirmaries and poor-law dispensaries look after the very poor, and our medical charities take charge of the comparatively poor, but one cannot see why our hospitals should ever forget the aims of their founders, and take it on themselves to make provisions for well-to-do people. The latter plan is absurd, and can only work harm. Year by year the hospitals are drawing more people, and seemingly pointing out that there is a growing mass of humanity unable to provide medical aid for themselves. This "grows by what it feeds on." At the same time, wealth is accumulating, wages are going up, hours of labour are shorter, breadstuffs are cheaper, while each person on an average spends £3 6s. 8d. per annum, or 1s. 4d. per week, on alcohol. Yet, medical fees are becoming less, while many doctors give their services and medicines to societies for 3s. 6d. per annum per member.

Hospital managers have made the mistake of confounding quantity and quality. It is the quality, not the quantity, of work done at a medical charity which gains support. Acting on their wrong idea, we have the "record" broken each year, always a higher number being quoted, so as to show the "increased usefulness of the institution"! The implicit credulity of some may be great, and sickly sentimentality will have its day; but people are now asking, seeing the improved condition of the working classes, "why this great increase of numbers, and why this treatment of the well-to-do by funds collected for purely charitable purposes?" In a few years the "record-breaker" hospital must be a thing of the past, for its own inconsistencies must kill it. Any system of charitable aid requires careful watching, else more than good follows. I have elsewhere expressed a great regret that the only way medical practitioners can advertise is through hospital appointments, and that little reform may be expected from them until they suffer in pocket. Our hospital authorities will not even attempt to define the question—"For whose use are our medical charities?" At present they are bidding for support, and with such strange statistics that even now many refuse to give support.

I would propose that our hospitals continue to be medical charities in the true sense, and then the many clergymen who at present dislike to preach Hospital Sunday sermons will help. A series of rules such as the following might be drawn up:—

1. That our medical charities be for the benefit of the sick poor and accident cases, and that our hospital committees meet and fix a "wage limit," thus deciding what class are eligible for relief.

2. That the Charity Organisation Society be supplied with a list of all those who apply, and that their inspectors inquire into the social circumstances of the applicants, as is now done in Manchester.

3. That all applicants be given treatment on the first occasion, but that second treatment be refused if the inspector has not "stamped" the hospital card.

4. That the plan of charging for drugs— thus puttting a premium on the quantity consumed—cease, and that all other charges, such as "entrance" or priority fees," be done away with. Thus patients would not be led to think that they "pay for what they get."

5. That the system of giving "tickets of reccommendation" to subscribers be abolished. These are frequently given by the employer to his servants, or to small shopkeepers. This plan would further prevent committees from giving offence to any subscriber because his ticket was refused treatment. Further, it would prevent those wage earners who gives to Hospital Saturday Fund from thinking they also can purchase treatment by their gifts. The Birmingham tickets of admission to the charities are sold at six for £1.

6. No salaries should be paid to any of the medical staff, nor should chaplains, auditors, or secretaries claim wages. At our eighteen hospitals £3,934 are paid to doctors, while the total wages amounts to £13,341.

7. The medical staffs of the hospitals should be greatly enlarged. This would prevent the doctors from running new hospitals "for the benefit of suffering humanity." Each hospital should have a full staff. At present there are no special departments, as for the eye, throat, ear, skin, and teeth at many of the general hospitals. If the staffs cannot be enlarged, then the hospitals might be opened in the evening (as is now done in London), a second staff being appointed.

8. The term of hospital service of a medical practitioner should be limited to five years. He might, after this, be drafted into another department. No practitioner should be allowed to hold more than one appointment. To illustrate, at our twenty Liverpool medical charities there are thirty-nine appointments for consultants filled by thirty-six men. There are ninty-one appointments for visiting doctors, these being filled by eighty-six men, some holding three separate posts. Out of a total of our 500 doctors in Liverpool, only 120 hold appointments at the hospitals. It is wonderful how some medical men object to any extension of the above proposal until a son is qualified as a medical man. As it now is, the public suffer, dissatisfaction exists, and new hospitals spring up.

9. The appointment of medical practitioners should be by open examination, as in the Army and Navy. To show the absurdity of the present plan, one doctor has been appointed because his future father-in-law worked him in. Almost every doctor who has a son about to become a medical practitioner looks upon him as the "heir apparent" to some hospital appointment. In Paris appointments go by examination. Here social influences and political opinions outweigh professional worth.

10. Workhouse and city fever hospitals should be open for teaching purposes, while their medical staffs should be enlarged.

11. If "pay wards" exist the paying patients should have the power to be treated by his own medical adviser, and also, if wished for, his nurse. This plan would do away with much friction, and would abolish, what is known as the "patient trap" scheme.

12. A public service should be organised, so that wage earners of 20s. to 35s. weekly wage might insure against medical treatment, either after the provident dispensary system or by the immediate payment of small fees, say 2s. the first and 1s. 6d. for subsequent visits to the doctor's office. Some of the working classes object to a "wage limit," but they do not object to their trades unions fixing the rate of wages or hours of work.

13. The various chemists should be asked to co-operate, and to draw up a tariff of charges—say 5d. for each prescription made up. This would allow all dispensing to be done by the rightful agent—the chemists—and it would prevent medical men from making a profit out of a drug business, or money out of the quantity of medicine swallowed.

14. The charity ambulances should not be used by the well-to-do, but each municipal authority should possess its own.

15. Police surgeons should treat police cases, and not send them to charities. Neither should club doctors get rid of their members by sending them to the hospital for treatment.

If the above rules were faithfully carried out, we should have no call for a Royal Commission, as the present sad condition of affairs is our own making. The diseased state has been recognised by all, and the treatment pointed out. There is no reason why Liverpool should not have one of the finest public medical services in Europe. All the implements are ready, and unanimity is only wanted. At present all the forces at work in our hospitals are destructive of self-help, self-respect, self-support, and self-reliance. Germany has now over 3,473,000 people insured against sickness and accident. A medical practitioner connected with a hospital said to me :—"Formerly hospital patients put on their old clothes, but now they come well dressed, and do not even take the trouble to pull of their kid gloves." We spend now over £8,490,000 per annum on our pauper population. Pauperism and want of thrift is hereditary. Why, then, do our hospital managers encourage it? The mere fact that a man pays one penny per week to a hospital does not prove that he is a fit subject for hospital treatment. Therefore "wage limit" of the subscriber—should the above scheme come in—must even then be settled. Finally, if the tax system is put in force, those practitioners acting on the hospital staffs will require to be salaried, as the continental plan.—Yours, &c.,

ROBERT RENTOUL.

THE COMPULSORY NOTIFICATION OF INFECTIOUS DISEASES.

To the Editor of The Provincial Medical Journal.

Sir,—The statistics in regard to notification which I compiled from the Registrar-General's returns, for the six years 1881-86, were sufficient, I think, to convince any unbiassed mind. But objection was raised that the period taken was not long enough, and that I ought to have differentiated between those zymotic diseases which under the dual system were notifiable, and those which were not. Now I consider any system which professes to lessen the mortality from zymotic diseases, as having failed in its mission, unless it can be shown to have lowered the death-rate from these diseases, as a whole, in the towns under its influence; just as the sailor fails to save his ship, if, in stopping one leak, he disregards others. And as to the period of six years, this was more than half the time during which the system had been at work. Nevertheless, being willing to meet any objection having the least show of reasonableness, I have pursued the investigation so as to obtain the averages for each of the seven principal zymotic diseases in each of the twenty-eight large towns, for the eleven years ending with 1887; and those individual averages I have reduced under the three groups of many original tables, not without considerable labour, owing to the needed adjustment according to population of the several towns, which I have carried out strictly. I beg to give you the results for the whole period and for 1887 separately, dividing the zymotic diseases as follows :—

Notifiable: Small-pox, scarlet fever, Diphtheria, fever.

Non-notifiable: Measles, whooping-cough, diarrhœa.

The towns in Group I., under no system of notification, are London, Brighton, Plymouth, Bristol, Wolverhampton, Birmingham, Liverpool, Leeds, Sheffield, Hull, Cardiff.

The towns in Group II., having been under the single or householder system during nearly the whole period, are Norwich, Nottingham, and Bradford.

The towns in Group III., under the dual system for periods varying in length from three years to the whole of that for which the average death rate is given, are Sunderland, Portsmouth, Halifax, Newcastle, Salford, Manchester, Birkenhead, Leicester, Derby, Bolton, Oldham, Blackburn, Preston, and Huddersfield.

Death rates in the twenty-eight large towns from the seven principal zymotic diseases in the period of eleven years, 1877-1887.

	Small-pox.	Scarlet Fever.	Diphtheria.	Fever.	Measles.	Whooping Cough.	Diarrhœa.
Group I....	0·179	0·544	0·159	0·298	0·578	0·720	0·915
Group II....	0·015	0.544	0·076	0·295	0·439	0·486	1·007
Group III....	0·034	0·561	0·112	0·362	0·639	0·581	1·136

Therefore, from 1877 to 1887 inclusive, the death-rates from notifiable and non-notifiable zymotic diseases were as follows :—

Group I., 3·393;	viz., notifiable, 1·180;	non-notifiable,	2·213
Group II., 2·863;	,, ,, 0·931;	,,	1·932
Group III., 3·425;	,, ,, 1·869;	,,	2·356

This, however, is open to the objection that some of the towns in Group III. were under no system of notification, for by far the greater portion of the period for which the zymotic death-rates is given. I therefore proceed to give the respective death-rates for 1887, concerning which there can be no mistake.

Taking the twenty-eight large towns we have the following death-rates from zymotic diseases :—

	Under no system.	Under single system.	Under dual system.
Small-pox	0·047	—	0·009
Scarlet Fever	0·366	0·288	0·502
Diphtheria	0·184	0·072	0·171
Fever	0·186	0·234	0·307
Measles	0·700	0·607	1·113
Whooping Cough	0·657	0·661	0·454
Diarrhœa	0·951	1·004	1·116
or Group I., 3·092;	viz., notifiable, 0·783;	non-notif.	2·308
Group II., 2·866;	,, ,, 0·594;	,,	2·272
Group III., 3·671;	,, ,, 0·989;	,,	2·683

This reveals the *startling* fact that in the year 1887, notwithstanding the high figures at Sheffield (under no system of notification), owing to the epidemic of small-pox, the towns which were under the dual system lost 206 per million more persons by *notifiable diseases*, than died of the same disease in the towns under no system! And if we could take the whole class of zymotic diseases together, as we properly should, they lost 579 per million more. If extended to the whole of England and Wales, the former number would present an annual slaughter of 6,000 persons, whilst the latter would represent a holocaust of upwards of 17,000! As it was, 1,100 lives were lost which but for the dual system would have been spared, this being the excess of zymotic deaths in the population of two millions under that system. If they had gone down in some big ship, the calamity would have met with a searching enquiry; but they departed noiselessly, leaving no record, except in the returns of the Registrar General. When will the country awake to the fact, that hundreds of lives are annually being sacrificed to a pet theory, which is as far removed from true sanitation as the East is from the West?—I am, Sir, your obedient Servant,

D. BIDDLE.

Gough House, Kingston-on-Thames.

THE ROYAL COLLEGE OF SURGEONS AND ITS MEMBERS.

To the Editor of The Provincial Medical Journal.

Sir,—The Council of the Medical Defence Union has decided to support Mr. Lawson Tait in his action against the Council of the Royal College of Surgeons, and the considerations which led to this decision may be of interest to your readers.

The Medical Defence Union is not concerned with the merits of the dispute between the College and its Members; but since Mr. Tait, as a Member and Fellow of the College, has been threatened by the Council with deprivation of his Fellowship and Membership, because in the course of the controversy he has followed what he conscientiously thinks to a be right and proper policy—the Council of the Medical Defence Union considers that it is a fit and proper case to be defended.

The position is simply incredible that Mr. Tait or any other Member of the College should be threatened with deprivation of the privileges of membership because be affixed his name to a document calling a meeting of the Members at the College.—We are, Sir, yours obediently,

LESLIE PHILLIPS, M.D., } *Hon Secs.*
A. G. BATEMAN, M.B., } Med. Def. U.

Medical Defence Union, Birmingham,
March 5th, 1889.

THE PROGRESS OF A YOUNG PRACTITIONER.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—In answer to "Junior's" letter in THE PROVINCIAL MEDICAL JOURNAL for February, I may give him my own experience. I think I am as successful as I could well hope to be. I qualified in 1882, and from that time till the end of 1887 I went about the world prospecting. I had a voyage to India, and acted as *locum tenens* and assistant in a great many parts of England, both in towns and in the country. I thus got a good insight into many kinds of practice, made friends in many parts of the country, and at last found an opening. This was not in a place where I had taken charge, but was recommended to me by a patient. I have been in practice in the place now for about twenty-eight months, and am making at least £300 a year, including a hospital appointment under the Local Government Board of £100 per year, and clubs which bring in about £40. I have spent out of capital £250, and I have, besides, a very small income; but I could have managed on the £250 easily if I had been more economical and businesslike. In the first year I *took* £112. For the first few months I was in lodgings; after that I took a small house and furnished it on the three years' system. For about eighteen months I had my dispensing done by a chemist. It is an expensive way of doing things, but avoids getting a stock of drugs before I knew if I should be successful. I may add that up to the present I have not had a quarrel with any one of the five other practitioners in the town; on the contrary I am good friends with all, and have, I think, done work for every one of them. I am thinking now of going into a larger house, and stabling a horse and gig. I ought to say that I am only of quite average ability, and did not distinguish myself in any way at my hospital except by protracted periods of laziness.

M.R.C.S. Eng., L.R.C.P. Lond.

THE CONSTRUCTION OR MISCONSTRUCTION OF PRESCRIPTIONS.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—The construction or misconstruction of prescriptions is a subject on which I think you might spare a small space in your valuable journal. Last winter, when laid aside through illness, my then assistant showed me a pocket copy of the Pharmacopœia of two London hospitals. On looking through, I invariably found after the magic ℞ the word "Aquam," and for the last few months the same word appears in your journal; in both cases the other ingredients of the prescription were abbreviated, so one could not say what case the writer would use. The writing of a prescription *in extenso* used to be the *pons asinorum* of my fellow students, but for the life of me I could not see why; the rule is simple—viz., after Recipe put all your drugs in the genitive case; your quantities in the accusative. In some cases the best of us will make a mistake, especially if the compilers of our Pharmacopœia go on adding a syllable at each revision to the already long words. In these days of pressure students are apt to copy what they see, and surely if at an examination they wrote "Aquam," they would come to dire grief. It is not "Aquam;" you do not Take water; but "Aquæ," Take of water. Small, is it not? Still might lessen one's average at a push. I do not set up as a Latin scholar, but let us not place any footfall in the way of the already harassed student.—I am, yours truly,

WILLIAM FRASER, B.A., M.B. Dubl.

Ashburton, Devon,
March 17th, 1889.

[☞ We would direct the attention of the writer to a correspondence on this subject in PROV. MED. JOUR., vol. v., p. 336, 382, 383.]

CASE OF LUPUS OF THE FACE.

To the Editor of THE PROVINCIAL MEDICAL JOURNAL.

SIR,—Last June I published a case of "Lupus" in your journal. I am now pleased to say that there has been no relapse. All the scabs have disappeared; all that is left is redness and thickening of the skin. This, I am afraid, will be permanent. The patient has persevered, and is still using the emulsion in the hopes of having a clear face. If no happier results than the total disappearance of the scabs, swelling, and discharge accrue, even then I think we have in the emulsion, thanks to Mr. Knaggs, an important agent wherewith to aid those who suffer from such a terrible and hideous disease as lupus. I expect in a few days to have an opportunity of trying this emulsion on another lady patient who is coming up from the country to see me, and I hope in a few months to be able to communicate to you another cure of this disease.—I remain, yours faithfully,

EUSTACE J. DE GRUYTHER, L.R.C.P., etc.

SIR WILLIAM MOORE, K.C.I.E., ETC.

SURGEON-GENERAL SIR WILLIAM MOORE, K.C.I.E., Q.H.P., M.R.C.S. Lond., L.A.C., L.R.C.P. Edin., received his education principally at the Queen's College, Birmingham, in the days when Sands Cox, and Birt Davies ruled that institution. On qualifying, in 1849, he was appointed Resident Surgeon at the Queen's Hospital, Birmingham, which post he filled for three years, leaving in 1852 to enter the service of the Hon. East India Company. He only retired from the Indian service last year, and we quote the following extracts from the *Times of India*, of April 2, 1888:

"Surgeon-General Moore, C.I.E., who leaves India by the mail to-day, entered the service as an assistant surgeon (as junior officers were then designated) in 1852. He is therefore now on his retirement in his thirty-sixth year of service, and is the senior medical officer of the Indian service now in this country. Coming to India in 1852 with an established reputation (having been awarded the Provincial Medical and Surgical Association prize of twenty guineas for the best series of medical cases published in the Association journal), he, instead of being retained in Bombay, was detailed for duty with the Rajpootana Field Force, where he served with the Artillery, with the Native Infantry, and was eventually attached to the First Light Cavalry Lancers. While serving in Rajpootana, he became acquainted with the late Sir Henry Lawrence, and also with Sir Henry's philanthropic views regarding hill schools for the children of European soldiers, views which years afterwards he furthered so well as honorary secretary to the Mount Aboo Lawrence Asylum, that it was recorded in 1877: 'It is chiefly owing to the kindly interest Dr. Moore has always taken in the school, to his unwearied exertions for its advancement, and to the care and judgment with which he managed its affairs, that the school is at the present time in so satisfactory a condition.'

"In 1877 Dr. Moore was selected for the post of Deputy Surgeon-General of the Presidency and Aden Division of the Army, which office he filled for the full term of five years. In 1884 he attained the highest post in his department, being made Surgeon-General at Bombay. Throughout his service he has been devoted to the extension of sanitation and the progress of medical science in India. His "Health in the Tropics, or Sanitary Art applied to Europeans in India," published so far back as 1862, may be regarded as the *avant-courier* of similar works. His later separate publications are "Health Resorts for Tropical Invalids in India, at Home, and Abroad;" a series of papers published under the title, "The other side of the Opium Question;" a second edition of a "Manual of Diseases of India;" and in December last a fifth edition of his "Manual of Family Medicine and Hygiene for India." Of numerous contributions to periodicals which have attracted attention may be mentioned articles in the *Calcutta Review*, being a "Review of Sanitary Progress in India," in which the immense improvements which had taken place up to date are recorded, and the requirements mentioned; and "The Eurasian Future," in which the increasing importance of the Eurasian population of India is urged. Surgeon-General Moore's professional position was to some extent acknowledged when his name appeared in the list of Honorary Surgeons to the Viceroy of India, and again in 1882, when the C.I.E. was conferred upon him."

On retirement from the service last year Surgeon-General Moore received the higher distinction of K.C.I.E., and was also nominated Honorary Physician to the Queen. Before leaving India the members of the medical service entertained him at dinner, and subscribed to a "Moore Memorial Fund," part of the sum realised being devoted for a portrait to be sent to Bombay, which is now being painted by the well-known artist, Mrs. Way, 46, Bedford Gardens; and the other moiety to form a scholarship or scholarships for the most deserving members of the subordinate Indian Medical Service.

Original Communications.

WHAT TO DO WITH THE DEAD.

By Fredk. A. A. Smith, M.D.

In writing this article, I am perfectly aware that much of it has appeared before in print; but as I find that many, very many, people are still quite ignorant of the facts here given, I deem it not out of place to go over some of the old ground; and as I intend giving some new ideas upon the subject, I hope the article, as a whole, may not prove uninteresting or uninstructive.

The question of what to do with the dead has more or less exercised the mind of man from time immemorial. At the outset of social life, it is true man thinks no more of his dead than do the majority of animals. He abandons them to the beasts, or birds of the air, and this form is seen in societies fairly civilised. Cicero says that in Hyrcania dogs were kept specially for eating the dead. The Bactrianæ also had their scavenger dogs. In countries where animal food is scarce, cannibalism is found to exist in some form or another. The Hindoos throw their dead into the Ganges, where they are devoured by fishes. The Bombay Parsees expose their dead in the silent towers. In some countries the dead are exposed on planks upon the trees; others bury them either in grottoes or tombs, or in the ground; others cremate—and of all funereal customs, this seems to be the most luxurious and the most coveted. In ancient Mexico that was a privilege reserved only to men of distinction. All these are simply different ways of getting rid of dead bodies. Cremation was also practised in North America. Among the yellow races, the abandonment of their dead was followed by cremation. In India it is common. We know also that the ancient Germans burned their dead, and pre-historic archæology teaches us that our ancestors in the stone age sometimes buried and sometimes burned their dead. The ancient Greeks and Romans also practised cremation; and among the Grecians it must have been held as something of an honour, for they refused the rite to suicides and other. As countries such as England become more populous, the solution of this question presents greater difficulties every year, and the time must come when radical changes will have to be made; for by our present system of burial we are yearly adding to our stock of dead bodies, which, in every stage of decomposition and horrible putridity, are poisoning the air and the water of our streams, and are the means of periodically starting fresh outbreaks of all kinds of deadly fever. These ills are naturally first experienced in London, whose population is said to double itself in fifty years, and from this statement, as regards this country, some idea may be gathered of our rapidly-increasing population. It has been proved by actual experiments that the air in and around graveyards teems with noxious gases and myriads of micro-organisms, ready at all times to attack the living with numberless diseases. The Right Hon. Sir Lyon Playfair, writing in 1885, said: "In most of our churchyards the dead are harming the living by destroying the soil, fouling the air, contaminating water-springs, and spreading the seeds of diseases. I have officially inspected many churchyards, and made reports on their state, which, even to re-read, make one shudder."

We will first inquire what becomes of a dead body buried in the earth. It is commonly understood that when a dead body is placed in the ground it remains there, and becomes part and parcel of it. Nothing is more fallacious. It matters not how you dispose of your dead, whether by burial in earth, by fire burial, the Feuerbestattung of the Germans, by exposure to air, by burial in quicklime, by solution in acids, the result is always the same—viz., the body is sooner or later resolved into its component elements, a very small proportion remaining in the earth as lime, phosphorus, iron, sulphur, magnesia, etc., which gradually become dissolved, and find their way to the water-courses. The gases, such as carbonic acid and oxide, ammonia, and others, are again decomposed by plants, and serve to nourish them. So you will by this observe how beautiful are the ways of nature, who, when allowed to have her own way unfettered—and mind you, her ways are the ways of God—allows of no waste; but as soon as life departs from a body, its elements are immediately utilised to nourish and sustain other living bodies in an endless cycle. The problem, then, to be solved is: given a dead body, to resolve it as quickly as possible into its component elements, with the least possible harm to the living. This is best done by a properly-constructed furnace, whereby the body is resolved into gases, which, mixing with the surrounding atmosphere, are immediately absorbed by plants, the two or three pounds of ashes remaining being perfectly white, inodorous, and harmless. That this solution of the problem is the proper one no thinking person, who has a due consideration for the living, will doubt, especially when the fate of bodies buried in the earth is properly investigated. Of course, I allude here to populous countries, such as England. One body more or less buried in the wilds of America, would not materially affect the health of its isolated inhabitants. I am willing to admit that many of the present objections are done away with by following the earth-to-earth system, as advocated by Mr. Seymore Haden, F.R.C.S. By this system bodies are buried in sandy, porous earth, in coffins made of the most perishable material, and the bodies are supposed to be resolved into their gases in about six years. But to follow out this plan properly, and allow each body to occupy one grave, a much larger amount of agricultural area would be required than this country could afford to lose. It has been said that one large deer forest and run, at present perfectly useless as regards supplying the country with food, would suffice to bury many millions of bodies. I grant this; but in the first place, an enormous sum would have to be paid to the proprietor for his land; and secondly, it would be practically impossible to transport bodies from all parts of the country to a national cemetery such as this would be—so that I think we may at once say that whatever is to be done with our dead will have to be done locally, each town and village disposing of its own. And again, the *great danger fraught to the living by germs* would still exist, as I shall presently endeavour to show. To return to our buried bodies, I shall not do more than give one or two examples, as the subject is too nauseating.

Dr. Cameron writes that in 1874 attention seems to have been called to the state of the parochial burying ground of St. Cuthbert's, Edinburgh, by the fact that a furnace had been built, in which the *débris* of coffins, dug up in the course of excavations of new graves, were consumed during the night, to the scandal and annoyance of the neighbourhood. Proceedings were ultimately taken under the Public Healths Act, and the evidence showed that in fifteen years 10,800 bodies had been buried in an acre and four-tenths of ground. The custom was to open each grave every

seven years, and what remained was burnt, to make room for fresh interments. The only apology that was attempted was that the same custom was followed in other churchyards, and I know that such is the general rule in England. It is also very common to dig huge pits, large enough to hold hundreds of coffins, which are laid in layers as they arrive, and practically left uncovered till they are filled, thus poisoning the air and spreading disease.

It not unfrequently happened that a very noxious drainage, from the piles of dead, accumulated in the bottoms of these common graves to the great detriment of the neighbourhood; and the writer of an article in *Land and Water* some years ago, said that in talking to the man in charge of a certain metropolitan cemetery, he is stated to have said, "You should go in there of a night and see them burning the bones and coffins." An eye-witness tells me that when the church at Hucknall Torkard, near Nottingham, where Lord Byron is buried, was enlarged in October, 1887, in digging out the fresh foundations piles of human remains were exhumed five feet high, and he saw a coffin plate bearing an inscription only ten years old: and a lady recognised the skull of her husband, who had only been buried eight years. To my mind this desecration of graves is simply dreadful, occurring as it does in a civilised country like England. I wonder how many would care to be buried could they only once see a section of a modern burial-ground with all its attendant horrors. You will see that these repulsive practices not only exist in connection with the burial of the poor, but that the rich also are not allowed to rest in peace.

It may surprise some to know that, to stop the possibility of the body bursting before it is buried, the custom among undertakers is to plunge a knife into the abdomen of the dead, just before screwing down the lid of the coffin. The gases generated after death are so powerful that they burst open the strongest coffins, even the leaden ones, and the acrid fluids, by setting up galvanic action between the solder and lead, eat holes into it and allow the putrid contents to ooze out into the vaults, and, filtering through their walls, poison not only the water but the neighbouring atmosphere.

It is not generally known that to enable our impoverished soil to bring forth yearly crops we import bones—many of them from the mummy pits of Egypt,—for which we pay nearly a million pounds sterling per annum. There is no doubt but that a very large amount of human bones, annually dug up in this country, are really sold and used for manure—the real truth being that few are safe from disturbance even in the grave. In the last annual report of the Metropolitan Public Gardens Association an analysis of 443 burial grounds is given; 116 have entirely disappeared, their sites being occupied by railways, docks, streets, etc.; 38 are turned into gardens, play-grounds for schools, stables, etc. How many thousands of tons of bones and other human remains were carted away? None can tell. I read only the other day that the Midland Railway Company were about to demolish St. Pancras Churchyard for extension purposes. This means the carting away of no end of human remains to be used as manure. I have given enough, I think, to show that as regards this country, burials are very bad indeed.

Another word in reference to the danger of earth burial in populous countries. Professor Darwin proved that the surface of the earth has passed through the intestines of worms, so that anyone dying, say from typhoid fever, and buried in the earth, would in time be brought back again to the surface, and the germs of the disease set free to poison the living. For it has been proved that the germs of typhoid can not only live, but actually thrive and multiply in damp earth. M. Pasteur has proved that the *Bacillus anthracis*, the germ of splenic fever or anthrax, also lives and thrives in the earth; and some years after burying a cow dead of this fever the soil over the grave poisoned some guinea pigs placed with it. In 1883 Dr. Friere, of Rio de Janeiro, in Brazil, found out the same as regards the *Cryptococcus zanthogenicus*, the germ of yellow fever, and Dr. Tomassi Crudelli the same as regards the germs of malarial fever. The same also has been proved as regards cholera by Professor Koch and others.

Tuberculous disease and even tetanus are due to bacteriæ which flourish in the soil. Also scarlet fever, typhus, small-pox, diphtheria, and others. All these germs can thrive in earth and live for a very long time, and are always a source of great danger to the living. I am informed that a plot of ground exists to this day in Bristol, railed in, which cannot be disturbed for fear of re-starting the plague, as people were buried there who died of that disease; and another place near the market, where people who died of cholera were buried.

The total number of deaths in 1884 was 530,828, of which 84,196, or 16 per cent., were due to zymotic diseases. The number in 1885 was 522,750, of which 68,972, or 13.3 per cent., were due to zymotic diseases.

Zymotic diseases include small-pox, measles, scarlet fever, diphtheria, whooping-cough, typhus, enteric, and simple fevers, diarrhœa, dysentery, and cholera. These are all preventable by proper hygienic means. I may here ask how many of our periodical outbreaks of different fevers are directly due to the dead in our midst? I cannot say, but fancy they all are. It is well understood that the only way to prevent contagious diseases of animals from spreading is to kill them, and to burn their bodies before burial. Why, then, should one rule be applied to animals and another to us, seeing that the dangers are exactly the same? There is a law in Lisbon making it compulsory to cremate all dying of infectious diseases, and I think the same should be done throughout the civilised world. It appears to be mostly forgotten by the rising generation, or perhaps was never known by them, that the state of our burial-grounds became so bad some thirty odd years ago that laws were passed prohibiting intra-mural interments, but this only puts off the evil day. Extra-mural cemeteries of to-day will be intra-mural in a few years' time. By intra-mural, I mean within the precincts of a town.

Various objections have been raised against cremation. As regards religious scruples, nothing is to be found in the Christian Scriptures enjoining burial or prohibiting cremation, and St. Paul, in his Epistle to the Corinthians, chap. xiii., verse 3, says:—"And though I bestow all my goods to feed the poor, and though I give my body to be burned, and have not charity, it profiteth me nothing," clearly showing that he looked upon cremation as a meritorious act in itself. It appears to have been abandoned by the early Christians, because burials could be conducted in secret, and so they could bury their dead with their own religious rites; and also because they, being ignorant of science, really believed that the buried body remains in the earth till called upon to rise again at the last day; and also, no doubt, because our Saviour's body was placed in a sepulchre, but it does not appear that He was really buried in the earth as we are at present, but more after the fashion of the early Christian in the catacombs. No intelligent

faith can suppose that any Christian doctrine can be affected by the manner of burial, and the martyrs who were burned, or eaten up by wild beasts in the arena, certainly died fully convinced of their salvation hereafter. Indeed, cremation gives truth and reality to the grand and solemn words, "ashes to ashes, dust to dust." Some fancy that, should cremation become general, the balance of nature would be upset, as no ammonia would escape if bodies were completely consumed. This is true, but plants do not absorb ammonia as such, any more than they absorb the carbonic acid, etc., as such, but they have the power of splitting up these different gases, and taking just what they require from them, and the elements of ammonia are always to be found, so I do not for a moment think the least difference would be made, *except that the living would be healthier.* In India, where so many are cremated and eaten up by fishes, and wild beasts, the balance of nature is not upset, but plants flourish most luxuriantly. The same elements are in the world now as always were, augmented, no doubt, by the daily deposits of meteorites and meteoric dust. They simply change their form: to-day, a gas; to-morrow, a plant; then an animal; and so on *ad infinitum.* It has also been said that should cremation become general, no pathological specimens would be found for scientific study; but, of course, specimens could always be obtained as at present. One gentleman I know deplores the idea, because had cremation always been practised, no fossil men would now be found, and thus again science would suffer. But fossil men are no longer required; instead, we have our sculptors and painters. Again, if the bodies of our dead are committed to public furnaces for cremation, it is said that Christianity would suffer no less than public morality and public happiness. I cannot for the life of me see why. As people become more educated, they will learn for themselves that, whether they like it or not, their dead must be burnt up eventually, and they only have to choose between a rapid and harmless burning up, or the more slow method, with horrid putrescence in the grave. Personally, I feel that to be sure of escaping the horrors of the grave, by being properly cremated after death, would make me feel very much happier in this life.

No doubt, pure sentiment is a very great factor to deal with in this question. The bare idea of being burnt up by fire seems, at first sight, to many, very dreadful; but it is only so at first sight, I should say, and a little calm reflection readily dissipates all the horrors. I confess I am very much astonished at the number of ladies who appear quite eager for this simple way of escaping from the horrors of the grave. Burying bodies seems, on the other hand, very dreadful to the mind of a Hindoo, and, as some one has very justly remarked, it becomes a question of purification *versus* putrefaction. Again, it has been said, that should cremation become general, great facilities would be given to poisoners; but I do not think so, especially as it is the rule that all bodies, before cremation, are opened, and the real cause of death certified by competent persons. In my opinion, everybody should be opened after death, and the true cause, if possible, certified. Not as a friend says, "to please the doctors," for, as a matter of fact, doctors as a rule would very much prefer to leave *post-mortems* alone, only knowing too well their disagreeable nature. But as a matter of public duty, this would be the best and surest way to put a stop to secret poisoning, and the chances of detection would be far greater when the bodies were opened fresh, than when exhumed and in a state of putrefactive fermentation. But many people strongly object to have *post-mortem* examinations held. I hardly know why, seeing that most of the crowned heads of Europe are invariably subjected to this process, and the rule is that the mass *will* follow the fashion.

When deaths from old age and natural decay, all zymotic or contagious diseases, acute and chronic diseases of the lungs, or other local organs, cancer, diabetes, rheumatic affections, childbirth, besides the five per cent. of unknown cases determined by the coroner are counted, a very narrow margin is left for doubtful examples. In fact, circumspection is necessary only in acute dysentery and diarrhœa, some affections of the brain, and in infantile mortality, especially as regards illegitimate children.

At present our burials are so lax, that, as was shown by Dr. Cameron in Parliament, over 30,000 persons die every year in Great Britain without any form of death certificate, and without having been seen by a medical man, often under circumstances suggestive of criminal neglect, or even worse; and matters are even more lax in Scotland, where there are no coroners, and where people may die and are buried without any official notice being taken of the fact. I believe it is the rule in some parts of Wales to be buried without proper certificates. The number of exhumations, compared with inquests, is about 1 to 3,000. Dr. Danford Thomas, coroner for Central Middlesex, held in seven years 10,000 inquests, and only three exhumations were ordered in that time. Again it is thought that should suspicious circumstances transpire after burial the body could be exhumed and examined, and poison perhaps found. But this is a popular delusion, which it would be well in the public interest to get rid of as soon as possible. It is true that certain mineral poisons can be detected after months or even years, but the more subtle organic and vegetable ones participate rapidly in the decay of the victims of the grave, and in a very brief space of time all trace of them disappears. Numerous modern researches have shown that putrefactive fermentation in decaying animal matter gives rise to the formation of septine and other alkaloids, some of them intensely poisonous, called ptomaines, and it is found impossible to tell whether the poison has formed after death, or was administered before. According to the experiments of M. Cadet, confirmed by Messrs. Dourvault and Wurst, all the mineral poisons have been detected in the ashes, except perhaps mercury. I simply mention this, not because I consider it at all important, because cases of poisoning would be far more likely to be detected, seeing that all bodies before cremation are opened, and the cause of death properly certified by competent men. In France, Germany, and other continental nations, a public officer is appointed, whose special business it is to see to these matters. He is called in France médicin vérificateur, and from a medico-legal point of view, the practice of cremation is rendered far safer than burial, as at present practised.

By this means, also, it would be impossible to bury a person alive, as is often proved to be the case at present. In fine, look at this question from any point of view you like, it is clearly the best known method of disposing of our dead. The system also would save no end of useless expense, whereby the rich are defrauded, and the poor thrown into debt. Over £800,000 are yearly spent in London alone for funerals. It is rapidly extending among civilised nations, and is legal in America, Germany, Switzerland, and Italy. In Vienna and Lisbon, where it is

compulsory in time of epidemic, and in Denmark, Belguim, Holland, Norway, and Sweden. In Paris a crematorium has been built in Père la Chaise, and an order issued for the cremation of hospital patients who have been dissected, and the commissioner of sewers is thinking of constructing a crematorium at Ilford for paupers. Wherever the question of cremation has been discussed, instructed scientific opinion has been in its favour, on sanitary and economic grounds. There are several crematories in use in different countries, but the one at Woking is after the invention of Professor Gorini, and it can reduce an ordinary body, at the expense of a few shillings, to some three pounds weight of ashes, perfectly white, in an hour. These can be placed in an urn, or otherwise disposed of by the friends. When cremation becomes general, how much better it will be to feel that no more horrible desecration of graves will be possible; and should the spaces of ground set apart for the reception of cinerary urns be required for building or other purposes, through the growth of the population, that the urns and ashes could be safely removed to other spots without violating the feelings of friends. In conclusion, I only hope that each year will see more fire-burials in our midst, and that some means will be found whereby local authorities will be enabled to promptly dispose of the bodies of their poor, instead of burying them in the present revolting manner, and that the intelligence of the public will show itself in a just appreciation of the safeties of this method, which will bring not only health and well-being to the living, but conduce to a proper respect due to the dead. Then that which springs from Earth to Earth returns, and that which draws its being from the sky, rises again up to the skyey height.

THE SURGICAL ASPECT OF RICKETS.[1]

By Edward L. Freer,

hon. surgeon royal orthopædic hospital, birmingham.

The time at the disposal of this meeting necessitates my confining my remarks, as the title implies, exclusively to the surgical aspect of rickets, without entering into its physiological and medical bearings. The surgical affections associated with rickets form a large proportion of the cases that engage the attention of orthopædic surgeons. Tibial curves are perhaps the most frequent deformities that we have to deal with. Every surgeon knows the cases of children with square-shaped heads, unclosed fontanelles, big bellies, enlarged epiphyses, barrel-shaped chests with headed ribs, and more or less curved legs. The fond mother, anxious to show how well "little Tommy" can walk, is constantly encouraging him to get on his feet, and the fact that many of these patients, by some miraculous good fortune right themselves, often induces the medical adviser to say that the child will "grow out of it." This is by no means always the case, and the number of children applying at the out-patient departments of our hospitals is a standing proof of the error of trusting too implicitly to an all-benign providence for a cure.

For slight cases of lateral tibial curves, under three years of age, I apply splints to the inner side, reaching from about two inches below the perineum to two or three inches below the inner malloelus, with straps at top and bottom, and a third at the greatest convexity of the curve. These splints have the double advantage of acting upon the curve, and of keeping the child off his feet. At first they should be worn continuously, but removed night and morning, for ablution with sea-salt and massage, to prevent wasting of the muscles. After a few months, when the curves are improving, the splints may be left off at night. For children over three years of age, and those with anterior curves, instruments should be tried for twelve months (in the latter case with a back bar from knee to ankle, and a double strap over the centre of the curve), when, if these appliances are not successful, osteotomy should be resorted to as a *dernier resort*. Genua valga require in young children somewhat similar splints, with a piece of webbing passing round the back from one splint to the other, a broad centre strap drawing the knee to the splint. Here the treatment may be assisted by passive manipulations night and morning with a pad between the extended knees. If instruments are required, they should be fixed at the knee, or in severe cases have a ratchet joint acting laterally, the instrument being applied in the deformed position, and gradually straightened from time to time with a key. Of the operations of osteotomy I am decidedly in favour of MacEwen's, as being far safer and more rational than Ogston's; and my results from this operation have been so successful that I should be unwilling to adopt any other. I prefer, however, to MacEwen's half-box splint, one devised by my colleague, Mr. William Thomas, which is very comfortable, and keeps the limb in excellent position. For anterior, and some very bad lateral curves, it is necessary to remove a wedge-shaped piece of bone, and in the former a back splint is required to keep the broken ends from riding up. I may add that I now invariably use the chisel, also suggested by my friend Mr. Thomas, which I call the "putty-knife," from its close resemblance to that instrument. There is far less chance of splintering than with MacEwen's, in consequence of the blade being thinner and broader. I have never myself had a case in which suppuration has occurred, and in the one or two cases I have seen, they have necessitated more frequent dressings, but all have done well. I must, however, enter my protest against a practice which has been adopted lately by some surgeons, —of putting these cases in plaster, and treating them as out-patients. We must remember that we have to do with simple deformities, and a procedure which might possibly be permissible in cases of accident, owing to undue strain or bad accommodation, or other causes, is, I consider, absolutely unjustifiable in these cases, where a little delay is of no practical importance; and were a death to occur to one of my patients so treated (a contingency not at all beyond the bounds of probability), I should feel myself morally guilty of manslaughter. I would also insist on the necessity, after osteotomy, of children at all events (and those in which the bones were found to be soft at the time of operation), wearing some retentive apparatus for at least twelve months, or until the rachitic condition has been replaced by the stage of eburnation, for I have met with several cases at the Orthopædic Hospital, where after operation elsewhere, the limbs were quickly retroceding to the abnormal state. Although many surgeons now perform these operations without antiseptics, I should be very unwilling to abandon such an important adjunct to the safety of modern surgery.

Redressement forcé has been suggested for these cases, and lately a formidable instrument has been described in the journals with this object, but taking into consideration

[1] A paper read at the Clinical Section of the Birmingham and Midland Counties' Branch of British Medical Association, February 22nd, 1888.

the uniformly excellent results of osteotomy, and judging from the appearance of the "osteoclast," I should much prefer to see it handed over to the contractor for bending tram rails, to making use of it for straightening leg deformities in human beings.

Pes valgus, or flat foot, is a very frequent result of rickets, especially when knock-knee exists and the centre of gravity is consequently thrown on to the inner side of the foot. A great proportion of children, when they first begin to walk, have flat feet, but the normal arches in these cases tend to develop as the muscles are strengthened by exercise. Light manipulations are useful in all such cases; when more deformity exists, I apply a light poroplastic splint to the foot while held in an adducted position; this the mother removes night and morning for manipulations and massage. In older children it may be necessary to apply a broad, well-fitting boot with a sole thickened on the inner side (Thomas' heel), together with manipulations and exercises to be later described. When still more deformity exists, and only a partial restoration of the arch is possible without much force, it is necessary to have some form of pad in the boot. I prefer super-imposed layers of felt to cork or india-rubber, as not so liable to cause corny thickening of the sole; or Holland's patent sole, which is light and effective, but rather expensive for hospital cases. The exercises here also must be systematically carried out. When the tarsal bones have become more or less fixed in the deformed position, the scaphoid being in some cases so much subluxated that the tubercle is in contact with the ground in walking, and there is actual contraction of peroneal tendons and ligaments, the only satisfactory treatment is by *redressement forcé, i.e.*, forcible manipulation under anæsthetics, sometimes also tenotomy of contractured tendons. This, however, is not nearly so frequently required as was formerly imagined. The apparent contraction is usually spasmodic, and in the majority of cases entirely disappears under the anæsthetic. The treatment, as laid down for milder cases, is even more necessary here, but for the first fortnight at least after the operation the feet must be kept in a state of extreme adduction by a padded malleable splint applied to the outer side, and a pad placed in each arch. The *redressement* may have to be done several times at intervals in very severe cases. The exercises I advocate are those suggested by Roth, and described in Kinesi-therapeutic language as "(A) Sitting foot inward circumduction forty times. (B) Sitting foot adduction (G.R.) and abduction (P.R.) twenty times. Walking on the toes, and, as the case improves, hopping on one foot, are also useful exercises. I have had numbers of most severe cases under treatment, and have never once seen a case that required osteotomy as suggested by Ogston, except a congenital deformity in the little child of a friend (non-rachitic), where there was an outward bend of the lower end of the tibia, which was rectified by osteotomy of the tibia and fibula.

One of the most important affections dependent on rickets is spinal curvature. The most frequent form is posterior curvature, which is very common in young children and often associated with pigeon breast. I recommend in these cases a malleable iron back-splint, covered with thin sole leather and padded, having elastic corresponding to the ribs, and laced in front, while to the upper part are attached elastic armlets to keep the shoulders back, and bands of swansdown, which can be replaced when soiled, attached below. When there is pigeon breast, a small pad may be placed over the projecting sternum. The exercises called breathers (alternate deep inspiration and expiration) are most useful in these cases, when the child is old enough to do them properly and systematically. Lordosis, or anterior curvature, is very frequently of rachitic origin; properly selected exercises, together with massage of abdominal muscles, are necessary in these cases.

Rotary-lateral curvature or scoliosis, when of rickety origin, is perhaps the least amenable to treatment of all rotary-lateral curvatures. We all know that when osseous changes have taken place in a scoliotic spine, to that extent or nearly so, is the deformity incurable; and while I hold that the majority of lateral curvatures are due at the outset to bad positions and relaxed muscles, which it is quite possible to detect before osseous changes have commenced, and that if we could insist on the prophylactic treatment of all young children in schools and at home by proper positions and rational free exercises, the number of scoliotic patients would be enormously reduced, still I must acknowledge that in rachitic children the osseous deformity is the primary condition, and treatment can only be directed to preventing its increase, and these are almost the only cases in which a body splint in the form of a divided plaster cuirass is indicated. This, however, should be removed at once whenever the patient can be entirely at rest on a couch or in bed, and the same exercises prescribed as in ordinary cases of scoliosis, special prescriptions being arranged for each individual case, and when the bones are sufficiently hard, and the muscular system developed, the cuirass should be dispensed with entirely. The rib-deformity is often much in excess of the rotary-lateral deviation, and therefore I insist especially on the exercises called "breathers" being carried out very systematically. I have reason to affirm by experience that the expansion of the lungs thus induced exercises the only improvement on the angular rib-deformity that it is possible to obtain. The other exercises I employ are too numerous to mention in this paper, several hundreds having been formulated from which it is necessary to prescribe those suitable to each individual case.

For further information I would refer you to Roth's Handbook, Von Ziemssen on Orthopædics, Schreiber on Massage, and other works. After each seance, which should never be of less duration than twenty minutes, massage of the back has a stimulating effect on the muscles, and also relieves the tired feeling that necessarily ensues. This treatment, far from being irksome to the patients, is a source of pleasure to them, and my patients, almost without exception, look forward to their daily course of exercise with delight.

I may mention that nearly all the cases of left dorsal curvature I have met with were of rachitic origin. I cannot leave the subject of curvature of the spine (and this after carefully noting their positively baneful influence for a period of nearly fifteen years) without cautioning all surgeons against those barbarous "relics of the Inquisition"—the so-called "instrumental supports."

I feel that my paper has been somewhat crude, but the subject is such a wide one that it was impossible to enter into the theories of pathology, etc. (which have been exhaustively dealt with in the numerous works on Orthopædics), unless I had devoted far more space than could have been allowed at this meeting, but I have attempted to prove to you my conviction that most of those unsightly deformities of rachitic origin that we see daily

in our streets are amenable to treatment by substituting simple common sense principles and the judicious exercise of our art for a "laisser faire" system on the one hand, and the indiscriminate assistance of the instrument-maker on the other.

REMARKS ON THE TREATMENT OF RHEUMATIC FEVER.[1]

By C. Orton. M.D.

RELIEF OF PAIN BY LOCAL APPLICATIONS A PROMINENT FEATURE.

In January, 1882, I published a short account of the "Treatment of Rheumatic Fever by Salicin and its Compounds," wherein I expressed my belief that these remedies, without necessarily being specific in their action, were in the highest degree useful in controlling the fever; and further, that in the local application of soda salicylate to the inflamed joints, was to be found a simple and efficient method of relieving pain.

I will quote three cases. I am indebted to Dr. Stokes Hatton for the notes of them.

Case 1.—R. S——, æt. twenty-five, potter; second attack. First attack seven years ago, since which time he has suffered from dyspnœa. Present illness of three days duration. Temp. 100.8°. He had a systolic murmur at apex and disastolic at base, both apparently old; heart large. The pains in the joints were relieved at once by the lotion, and quite gone in about fifteen minutes. Temp. normal in twelve hours, but on the fifth day rose again after medicine had been diminished and the lotion suspended, subsiding again under treatment next morning, and there was no subsequent rise of temperature, and no return of any pain. No alteration in the cardiac symptoms occurred during the illness.

Case 2.—A. F——, æt. thirty; first attack; ill fourteen days. No joint free from pain. Temp. 103°. Pain began to abate as soon as lotion was applied, and ceased in from half an hour to an hour, and never reappeared. There was no cardiac affection at any time. In twelve hours temp. fell to 100.4°, and became normal in fifty-eight hours.

Case 3.—J. B——, æt. nineteen; first attack; ill three days. No cardiac mischief. Temp. 103.2°; fell to 100° in thirty-six hours, and became normal in forty-eight hours. Pain subsided immediately, but reappeared in other joints, though but slightly. Treated with same result.

Now the relief from pain gained in these cases is a fair sample of what I have met with in practice; but the relief from pain, though highly gratifying to the sufferer, does not constitute the cure, or the end of the complaint. Without caution it may even do harm, by raising the false belief that because the pain has disappeared the disease is cured, and the patient naturally ventures to do more than is good for him. Here are two illustrations. 1. I wrapped up the affected joint—the left ankle—with the lotion in the morning; the pain began to subside at once; was quite gone in half an hour, and the patient walked down stairs in the afternoon, and was surprised when the right ankle became still more painful than the left had been.

The second case was one from a neighbouring county on a visit, who had had two previous attacks. I found the wrist much swollen, red, and very painful. I put it up at once, gave a prescription, and advised her either to go home at once or go to bed. She did neither. The pain disappeared. She went out for a walk; did not even get the prescription made up; and I need scarcely say that I was summoned again the next day, and remained in attendance a few weeks. You will perhaps pardon me for quoting a minister of religion on this subject, but he put it fairly and pithily. I had attended him for a second attack of rheumatic fever. He says, "I do not think that the treatment has shortened the attack by a single day, but in my first attack the pain was excruciating, for which I had to take opiates. In this attack I have had no pain worth mentioning after the first application of the salicylate."

This fairly represents my opinion. I do not make out that the salicin treatment will get a patient out of the hospital twenty-four hours sooner than some other methods of treatment; and, further, unless you are careful to continue the medicine, you are exceedingly apt to get a relapse, and I invariably combine, or follow up with, bicarbonate of potash. I willingly acknowledge that the treatment by salicylate of soda is the most successful I have ever tried, for as pain is the leading and prominent symptom of rheumatic fever, and relief from pain the first—if not the great—consideration, I claim that in the vast majority of cases even with small doses, so as never to have any toxic effects, the combined treatment of internal administration and external application of soda salicylate has given in my hands almost instant and lasting release from pain, and reduced the temperature; but I cannot go with Dr. Maclagan, when he claims that it cuts short an attack. No! Salicin is not the specific in rheumatic fever as quinine is undoubtedly in intermittent fever.

You may ask, have I had no failures even in the relief from pain; well, not many; but I have, and when I look back over my cases it strikes me that in those cases where the perspiration was most intense, where the acid smell was most marked, where, in fact, I suppose the greatest amount of lactic acid was either being formed or retained in the system, there certainly was the effect of the local application very unsatisfactory. This failure of one remedy in certain cases naturally makes one pause to consider whether a certain train of symptoms is always due to one cause. Dr. Maclagan argues very cleverly that the cause of rheumatic fever is of malarial origin. A distinguished member of this branch (Sir W. Foster) still holds, I believe, the idea that lactic acid is the cause, and quotes a case which, in my opinion, Dr. Maclagan has not explained away.

In one of my last cases treated (a most offensively acid one) the cause could not possibly have been of malarial origin. Here I obtained more relief from salines and opiates than with the salicylates. In a still later case the cause may have been malarial, and here the pain was gone within fifteen minutes. In the subacute forms of so-called rheumatism nearer allied, in my opinion, to gout, the lotion has no special action.

Further Remarks.—The above paper was read on Feb. 23rd at the meeting of the Staffordshire Branch, held at Stafford. On Feb. 25th the *B.M.J.* gives us the exhaustive report on Acute Rheumatism of the Collective Investigation Committee. I beg to point out that under the head of "Cases in which Salicin, Salicylic Acid, or its Salts Failed," no less than seventeen of them are reported by different observers to have had profuse or considerable

[1] Read at the Staffordshire Branch Meeting, Stafford, February 23rd, 1888.

perspiration. In my experience, as I have said before, it is in these cases of profuse acid perspiration that I have failed with the salicylates, and I had come to the conclusion—unlike the one arrived at in the report—that it would be better to begin with the saline treatment at first. At any rate, I believe that, so far as the salicylate of soda is concerned, if it is going to be of any use at all, its beneficial effects are very markedly and very speedily shown, and valuable time may be lost in persevering with the treatment unless benefit begins to accrue—I may almost say—within the first few hours.

CASE OF RELAPSING TYPHLITIS—RECOVERY AFTER ASPIRATION (2)—EXTERNAL INCISION, WITH REMARKS.[1]

By Frederick H. Alderson, M.D.

The disease termed typhlitic inflammation of the walls of the cæcum, or its appendix, has occupied the attention of the profession rather prominently of late. The Medical Society of London, after a most able and suggestive paper by Dr. Bull, of New York, "On the Surgical Management of Typhlitis and Perityphlitis," devoted the evening to its discussion. More recently, Sir Dyce Duckworth has published a clinical lecture in the *Lancet* "On the Symptoms and Treatment of Typhlitis." The attention, too, of this society has incidentally been called to this interesting and important disease by our late excellent president, Mr. Keetley, in his practical paper on "Tubercular Peritonitis," and on that occasion in the after discussion I narrated a case that occurred in my own practice of typhlitis in a delicate boy of fourteen, whose recovery resulted after aspiration (2) and an external incision, when alarming symptoms had very plainly shown themselves.

It is now my pleasure to show you this patient, who, after the long period of two years and a half, has continued perfectly well, and whose recovery, after the external incision, proceeded (excluding the sinus) uninterruptedly; and, in fact, he is now a much stronger youth than he was before his attack of typhlitis, when he was a somewhat delicate and backwardly developed boy of fourteen. I purpose to read from a few brief notes of the case, and to offer some remarks on the cause of the attack, the prominent symptoms, the treatment, and the general prognosis of typhlitis, and also a few words as to the prevention of a relapse. In the meantime, I would ask your examination of the patient, directing your attention to the locality of the abscess, to the pale cicatrix of about an inch and a half in length, perpendicular to, and about an inch above, the centre of Poupart's ligament, denoting the situation of a sinus—that at one time was indolent and persistent—and also to the character of his inguinal hernia, which bulges here, and remains as the permanent legacy of his illness.

I attended this youth, E. V——, then a lad of fourteen, in 1886, from July 6th to July 17th, with what I then thought was a gastric feverish attack: he had a dirty tongue; suffered from retching, constipation, anorexia, and slight rise in temperature. He complained of stomach-ache, and of pain in the right inguinal region. There was no signs of any hernia, but some indistinct history of a previous sprain. After a week's rest in bed, gentle aperients, and saline mixture, he was quickly convalescent, and returned to school after a fortnight's absence, rather against my wish; but as his studies were important, and his temperature normal, I gave a reluctant consent.

On August 2nd I was again called to attend E. V——, but this time he was evidently more seriously ill. The symptoms were the same, but more severe, and at first rather suggestive of typhoid; and I carefully searched for spots, but discovered none. There was much more pain, which radiated all over the abdomen, but appeared to originate, and was more severe, in the right iliac fossa. After ten days there was distinct tenderness, and a slight fulness over the cæcum. This apparent distension of the cæcum was at first considered as a proof of the possible typhoid type of the fever, but there was never any gurgling; nor, indeed, at any time any serious doubt that the illness was not typhoid, nor of any of the infectious fevers. Nausea and sickness were now prominent symptoms; the abdominal pain was almost constant, and was more diffused; the tongue was furred and brownish. These symptoms continued for about a week, alternating with remissions, and occasional paroxysms of pain; but on the 10th he appeared easier, the sickness much better, the bowels relieved, and the temperature 100°. I decided to attend the British Medical Association meeting, leaving him in skilled hands.[1] On my return from Brighton on the 16th I found the symptoms much more pronounced, and no doubt as to the disease; and there was now a decided and prominent distension of the right iliac fossa, and acute tenderness, and the general aspect and prospect of peritonitis. On my evening visit I found him very ill; temp. 103°, and in very great pain. He had on Sunday passed a very restless and painful night, and on the Monday morning the temp. had risen to 104°. He had another bad day, and on the early morning of the 17th I was hurriedly called to him by his parents, who were greatly alarmed, for he had had no sleep, and had been in agony all night. The temperature was 104.3°; the pulse small and rapid; the breathing short; pain all over abdomen, but much more severe at the seat of tumour (for the swelling was now increased and prominent). The condition of the patient was one of great danger; that pus was present there was not the slightest doubt, and if it was not promptly got rid of, I felt that the boy must die. I decided to empty the abscess by the aspirator, the patient being highly nervous and excitable, and the swelling very sensitive even to the slightest touch. I proposed that he should have chloroform: this was given by my friend, Mr. Alderton, whose opinion, too, I was glad to have, and who quite thought with me that aspiration promised the quickest and safest relief. I drew off by the aspirator about a pint and a quarter of dark green, vilely-smelling, pus, and as I withdrew the needle we noticed *a few bubbles of gas*. Mr. Alderton also remarked to me the distinctly *fæcal odour* and character of the pus. Immediate and great relief resulted, and on my visit a few hours after the aspiration the temperature had fallen to 100°. E. V—— slept well the following night, but it was soon evident that the abscess was refilling, and that the encouraging results were only temporary, for as the abscess refilled there was a return of both pain and fever. I aspirated on the 19th, Mr. Alderton administering chloroform, and this time three quarters of a

[1] The patient was shown, and the case described before the West London Med.-Chirurg. Society, at their Clinical Meeting, Jan. 4, 1889.

[1] I would here gladly thank my *locum tenens*, Mr. Ernest Thompson, now of Kirkham, for his management of the case during my temporary absence.

pint of the same ill-smelling pus was drawn off, and the same immediate relief of symptoms followed, the temperature almost at once falling to normal.

After this second application the abscess filled now with greater rapidity, and two days afterwards was much more superficial, and fluctuation easily detected; the patient was evidently better. I decided on the 21st to treat it as an ordinary abscess, and opened it with a Syme's knife, and inserted a large drainage-tube, and covered abdomen with linseed poultice, and over this a layer of tenax. Pus flowed very freely from the drainage-tube, both through and at the sides of the tube; the first few poultices, and also the tenax, were saturated with pus. I washed out the abscess night and morning by syringing with carbolised hot water, and then injected weak solution of tinct. iodi., and later on Zn. SO_4 v. Ag. NO_3.

After the external incision there was never any rise of temperature, and the progress towards recovery was continuous and uniform. After a few days, when both poultices and tenax were profusely saturated with pus, suppuration slowly but perceptibly declined; but after the removal of the drainage-tube a fortnight later a sinus of three or four inches in length remained, and a part of this refused to heal, and threatened in spite of all stimulation to become persistent (although up to this date, and ten days later, the patient had not left his bed). I therefore laid it open with an ordinary bistoury, and then dressed with zinc lotion, and it soon healed. The sinus previous to incision had contracted, and was considerably reduced in size after pressure by coin pads, and the application of a well-adjusted spica bandage.

On September 12th E. V—— left home for Ramsgate quite well; but on his return after a month's residence at the sea, I found the wound continued perfectly sound, but inguinal hernia now existed at the seat of the former abscess, for which I ordered a hydrostatic truss, and this he continues to wear, and is very comfortable.

This is the history, the treatment, and recovery of this youth from a no slight attack of typhlitis; that it was a grave attack there is no doubt, and was not one of those least dangerous forms as Sir Dyce Duckworth described, that in an early stage "present an iliac tumour, involving only the caput coli, and not the appendix (in my patient there was no decided swelling of the iliac fossa until a comparatively late period of the illness), and it is just these cases of delayed iliac swelling that are usually the most urgent, and the more likely to prove fatal."[1]

That the disease originated in the appendix is most probable, for all authors appear agreed that it is the vermiform appendix of the cæcum that is the part involved in 70 per cent. of the cases of typhlitis; and that the bowel was the seat of the abscess may, I think, be said to be proved by the gas bubbles that escaped on the withdrawal of the needle, and by the vilely fæcal odour of the pus. The causes of typhlitis are generally limited to two—catarrhal inflammation, or intestinal irritation—and it is almost invariably due to an irritant when the appendix is the lesion affected. I feel rather confident that this illness was due to irritation produced by habitual constipation. There was a distinct history of confined bowels; this may have been caused through the neglect of the boy to attend to nature's calls. He went to the City of London School, a distance of over five miles from his home, and had to walk a mile to get to the station, and to be at school by 9 a.m. He told me in consequence he had often to hurry over his breakfast, and no time to go to the closet; and, as he said very often, he had to drive off the action of his bowels.

One or two remarks as to the symptoms: the pain at first was rather misleading, and was described as stomach-ache; yet on closer examination, although it radiated all over the abdomen, it could always be found that it originated from the right iliac fossa. I would like also to direct attention to the invidious nature of the early symptoms—that induced at the beginning of illness the suspicion of typhoid—that crossed my mind, and that the exacerbations of the evening temperature, and the looseness of the bowels after the mildest aperients, to some extent gave credence; but this suspicion was of the briefest duration, as I never seriously thought that it was any form of infectious disease that I had to treat. E. V—— had one symptom, however, that I very particularly remember, and that was a distinct resistance to touch, especially on the slightest palpation. Now this resistance of the right oblique, the transversalis and rectus abdominalis muscles, is a symptom of typhlitis that can be early noticed, and is particularly mentioned as of importance in the lecture of Sir Dyce Duckworth, to which I have already referred. As regards treatment, physicians state that typhlitis is a malady not without risk, but that it will get well by rest and opium; and, as Dr. Bristowe adds, with leeches.

In a leading article in the *Medical Press* for November 12th, the editor writes: "In 70 per cent. of the cases, however, the appendix itself is the starting point, and the subsidence of the symptoms is likely to be followed by recurrence unless the offending portion of the gut is removed." Again in an editorial article on "Perityphlitis," February 27th: "The risks to life of relapsing perityphlitis are only to be successfully dealt with by the patient submitting to laparotomy."

Now because my patient has made so good a recovery, and because I am able to show him to you quite well, and without having had any relapse after so long an expiration of time (now almost three years) that I think possibly that this opinion may be rather too surgical.

Mr. Bull told the Medical Society of London that he had separated his cases of typhlitis that required surgical treatment into three groups. The first consisted of ten cases in which the abscess was opened by incision through its walls without opening the general peritoneal cavity, at periods varying from seven days to six weeks—they all recovered. The second group comprised six cases in which the peritoneal cavity was opened seven times for supposed perforation of the appendix, with developing peritonitis; the earliest thirty-six hours after symptoms; the latest on the fifth day—*death followed two.* The third group was represented by a single case: the abdomen was opened in the presence of threatening symptoms on the twelfth day of a perityphlitis: no pus was found, nor were there any evidences of recent peritonitis, but the appendix was buried in a mass of old peritoneal exudation.—*Vide Lancet*, November 10th.

Now the removal of the appendix must, I should think, be regarded even by an heroic surgeon as a serious operation; yet I incline to think that had this youth fallen into the hands of an expert surgeon, confident in his skill in operating, and judging that the brief illness in July was an attack of typhlitis (and I have no doubt now that it was), he might have thought it right, and the more effectual treatment, to have performed a complete laparotomy, and to have removed the appendix..

Now the vermiform appendix may be, as a distinguished

[1] Vide *Lancet*, October 6th, 1888.

pathologist has said, merely a receptacle for "the cherry-stones that children accidentally swallow"—only a nidus for all manner of indigestible and forbidden food; but it is eight or nine inches long, is often found to contain fœces, and is not wanted for ornament or uniformity. Is it therefore unreasonable to suppose that it may have some unknown use, that further light may show, and further research and experiences prove, that it may be worthy of more consideration than perhaps it has yet received, either from the brains of physiologists or at the hands of the surgeons? The best prophylactic is not, I think, the extirpation of the appendix, but rather, the future safety of the patient is in the avoidance of chill, and in the careful attention to a well-selected regimen, eschewing melons, figs, oranges, or any article of food that contains seeds, pips, or that is indigestible, and particularly to promote a daily matutinal action of the bowels.

As to the special and milder surgical measures used in the case before us, I would mention that although the aspirations did not cure the patient, did not prevent the speedy re-secretion of the pus, yet they gave immediate relief, at once removing the pain and rapidly reducing the temperature. But aspiration did more; it gave the patient strength; it enabled the boy to take nourishment, and afforded time for the abscess to mature and the pus to come almost to the surface, so that fluctuation was easily detected; and time, too, for the abscess to become more circumscribed, for its walls to strengthen, and to become stronger, shutting off more effectually the peritoneal cavity, and reducing the chances of any unfavourable sequelæ, thus rendering the external incision a trivial operation to what it might have been at the time of even the first aspiration, and specially at an earlier period of the illness, when the abscess was evidently more or less deeply situated.

With regard to the medical treatment, my own observation confirms the remark of the boy's mother, that he was always better after action of the mild aperient given. The small but frequent doses of grey powder, or soda and grey powder, relieved his sickness, and when followed by an occasional enema of warm water, or warm water and opium, eased his pain, and action of the bowels sometimes resulted. Opium, with and without belladonna, was given internally, and often with relief more or less of acute pain, but I think Mr. Lawson Tait's is a wise and timely remark as to the "not infrequent need of caution in the administration of opiates for continued abdominal pain, especially in cases of long-continued inaction of the bowels." I can never forget a case of chronic typhlitis that occurred in an elderly lady whom I attended, and to whom by the advice of the consulting physician who had seen the patient with me (three times in the week of the lady's death), I gave opium, or opium and belladonna, frequently for nine days of continued total constipation of the bowels, and who died quite suddenly immediately after a first and sudden attack of fæcal vomiting. The *post-mortem* revealed no obstruction, but intense enteritis, a large cæcal abscess, and the intestines greatly distended with fœces. There can be no doubt that opiates tend to paralyse the bowels and increase silently the mechanical congestion. A word or two in conclusion as to the locality and the cicatrix. Sir Dyce Duckworth, in his lecture, calls attention to the observation of Mr. Treves: "That the cæcum is most frequently situated not in the right iliac fossa, but in the fascia of the psoas muscles; but a meso-cæcum does, however, sometimes exist, hence you may meet with a cæcal or appendicular hernia." This is what I think we may have here, for if the abscess had been on the psoas the boy might probably have been lame, at any rate for a time, and not able, as he was, to swim almost within a month of opening the abscess. A pale cicatrix marks the situation of what at the least was a much larger sinus than the remaining scar. Mr. Knowsley Thornton says these sinuses are very apt to become persistent, and very apt to occur if the patient is not kept in bed, and are "usually quite incurable."

In speaking of the prognosis of typhlitis, Dr. Bristowe, in his "Theory and Practice of Medicine," at page 667, writes: "Sometimes the patient recovers; sometimes he lingers for months or years with a constantly discharging abscess, or succession of abscesses."

As a closing remark I would mention that it occurs to me that cases of typhilitis are more common than is generally thought, and especially, perhaps, is this the case in young children. I believe many a case of what may be termed, or is called, febricula, is really mild typhlitis, and if the child could speak, or was old enough to express his feelings, would complain of pain in the right iliac fossa. Indeed, I have in some such cases as I refer to, noticed a puffiness, if not a decided swelling, that was not a hernia nor "a windy rupture," as our poorer patients often term a swelling in an infant's groin (I am speaking as to my own experience). But if the illness is slight, and these cases recover, they are forgotten; but perhaps at early puberty (and they are generally boys) these little patients may become the victims of more or less acute typhlitis. If the symptoms are not acute but insidious, and they recover, these attacks may even then pass unrecognised, or perhaps be mistaken and euphoniously called gastric fever, or a gastric attack, especially if the symptoms are not urgent and the recovery rapid. The term gastric fever ought, perhaps, never to be used by a well-informed medical man; yet who of us do not use it occasionally, for the term is convenient, and it does not alarm? Although not exact it is more or less truthful, for there is nausea, or sickness, and there may be fever and pain, and the public look coldly upon the doctor who cannot, or who does not, give a name to the disease he has to treat, so "gastric fever" or "a gastric attack" will continue to be used; and like as Dr. Maudsley once said of congestion, that it was like unto charity, for it covered a multitude of sins, so also will the term gastric fever be more or less frequently used, pleasantly covering many varied omissions and not unpardonable errors; but this mis-naming disease, if used seriously and without due thought, is scarcely to the credit of medicine, or in accordance with the exactness of a science, or even to the advantage of the patient.

Note.—The appendix appears as if it dilated and shortened *pari passu* with adult life. I have noticed in some youths (and in my early professional life I made a great many *post-mortems*) that it is sometimes much longer and narrower than is usual.

THE PROSPECTS OF MEDICINE IN AMERICA.[1]

By A. R. Baker, M.D., Cleveland, Ohio.

The present is a transitional period in the history of medical education in America. Our system of medical instruction has been of gradual growth, and peculiar to this country. The first physicians who practised scientific medicine in early colonial days were educated abroad. But the supply was not equal to the demand. "In 1776

[1] Opening Address, Medical Department of the University of Wooster, February 27th, 1889.

it has been estimated that there were not two hundred graduates of medicine in the country, and not over three hundred and fifty practitioners of medicine who had received a liberal education." Young men without previous medical education were taken into the office of practising physicians, for whom they rendered such assistance as building fires, taking care of the horses, dispensing drugs; and, in the course of a few months or years, were permitted to see emergency cases and visit patients. Thus originated our peculiar institution of medical preceptors. Many of the early practitioners of medicine never attended a medical college. There were no such schools in this country, and few could make the long voyage across the Atlantic to attend the European medical institutions. And we are told that even "during the early part of this century, almost the entire body of men who entered the profession, entered through examination of one of the 'Boards of Censors,' as the examiners were called who were appointed by the State medical societies and their auxiliaries." In this way, "these societies were the principal agents in fixing the standard of medical education; and although after the establishment of medical schools, the diploma of one in good repute was accepted in lieu of an examination, this was by courtesy rather than by law." The tendency of present medical legislation in several states is to return to methods similar to those tried in the last century and found deficient. I hope it will prove more satisfactory in this.

The medical colleges were the natural outgrowths of the system of medical education in the preceptor's office, and, consequently, systematic courses of medical instruction were not attempted at an early period. They were not endowed or supported by the State, but depended upon the fees of the students. They, "like many institutions peculiar to America, were called into existence by the necessities of the time." Medical students would naturally seek physicians of wide reputation as preceptors, where they could have the advantages of a library, and possibly a few "bones," or even an entire skeleton. It was in the office of this practitioner that the student gained his first knowledge of medicine and surgery. "Here he pulled his first tooth, opened his first abscess and performed his first venesection, applied his first blister, and administered his first emetic." "His clinical lectures were heard as he rode from one patient to another with his master."

Three years of such study were necessary before entering upon practice, the same length of time required now. As the reputation of a physician became more famous, students came to him in greater numbers. Gradually his lectures, given upon horseback as he rode through the country, took a more formal character, and were delivered in his office, or possibly in some public hall. This formed the nucleus of a medical school. "Several such teachers united their efforts, and thus were organised the medical schools of Philadelphia and other cities." The first authentic record we have of dissections having been made, for the purpose of imparting medical knowledge, was in the year 1750, at which date Drs. Bard and Middleton, in the city of New York, "injected the blood-vessels of a body which they dissected for the instruction of several young men engaged in the study of medicine." It is quite probable that similar dissections were made prior to this date by other physicians, of which no record has been preserved.

According to Dunglison, in 1754—56 a course of lectures on anatomy and surgery, accompanied by dissections, was delivered at Newport, Rhode Island, by Dr. William Hunter, of Scotland; and in 1762 Dr. Shippen, in his anatomical lectures at Philadelphia, laid the foundation of a medical school, now the University of Pennsylvania. It was organised upon the plan of the Edinburgh Medical School, and has been the pattern which all our colleges have imitated. In 1767 steps were taken for the establishment of a medical school in New York, which is now known as the College of Physicians and Surgeons. In 1782 the Medical Department of Harvard University was organised by Dr. John Warren, and was located at Cambridge, Massachusetts. The fourth medical school instituted in this country was that of Dartmouth, at Hanover, New Hampshire, in 1797. These were all the medical schools established in the United States before the beginning of this century. Thus it will be seen that the establishment of medical colleges is of comparatively recent date, and that the great mass of physicians, in the early history of the country, received their medical education in the office of the preceptor. This method of study has its advantages: while it does not, as a rule, make scientific practitioners, the medical man educated in the physician's office has many advantages over the one educated in the medical school. He has abundant opportunity for clinical observation; he is trained daily in the art of prescribing and dispensing medicines; he learns many of the essentials of a successful practitioner which cannot be gained in the lecture-room, or even in hospital and dispensary practice. Our patients suffer from mental ills as well as physical ones; and the secret of retaining their confidence during serious illness, or during the meddlesome interference of some busybody, can only be learned by practical experience, and this experience can be gained nowhere so advantageously as in the office of a successful practitioner. But notwithstanding the many advantages of study in the preceptor's office, this time-honoured custom is fast becoming a tradition of the past. The average medical student of to-day is not willing to sweep office, build fires, groom horse, care for children, and make himself generally useful to the doctor's family, in order to pick up the few crumbs of medical knowledge which may be dispensed by the way. The increased time spent in attendance upon medical lectures leaves but little time for study in the preceptor's office. The writing of prescriptions has dispensed with much of the necessity for the student's assistance in compounding medicines. Sharp professional competition makes it necessary for the physician to give his patients his personal supervision. He cannot turn them over to the tender care of the medical student as formerly. These are but a few reasons why the position of medical preceptor is becoming of less importance from year to year, as a factor in medical education. All endeavours to elevate the standard of medical education must take this fact into consideration—viz., that *the medical preceptor has served his day and age, and must be numbered among the antiquated institutions of a pioneer civilisation.*
